#### Abstract

This atlas contains sample spectra from the far-ultraviolet observations of 32 symbiotic stars obtained with the International Ultraviolet Explorer (IUE) satellite. In all, 394 low-resolution spectra from the short-wavelength primary (SWP) camera covering the range $1200-2000 \AA$ have been extracted from the $I U E$ archive, calibrated, and measured. Absolute line fluxes and wavelengths for the prominent emission lines have been tabulated. Tables of both the general properties of these symbiotics and of features specific to the spectrum of each are included. The spectra shown are representative of the different classes of symbiotic stars that are currently in the $I U E$ archive. These include known eclipsing systems and those that have been observed in outburst (as well as quiescence).

Subject headings: binaries: spectroscopic — line: identification — ultraviolet: stars

## 1. INTRODUCTION

Symbiotic stars are believed to be interacting binaries embedded in an ionized common envelope formed by a stellar wind lost by either one or both members of the system or by material that has been ejected during outbursts. Symbiotics generally consist of an M giant, which is often a Mira or latetype semiregular variable, and a hot companion with an effective surface temperature in the approximate range $25,000 \mathrm{~K} \lesssim$ $T_{\text {eff }} \leqslant 100,000 \mathrm{~K}$, appropriate to white dwarfs or the central stars of planetary nebulae. In a few cases, the presence of a main-sequence star is suspected. In many of these systems tidal interaction is believed to form an accretion disk around the compact secondary. The formation of hot accretion streams that results from the tidal interaction between the binary members may explain the presence of high-excitation permitted and intersystem emission lines that characterize symbiotics in the optical and UV.

Orbital periods of symbiotics vary from two to several dozen years. In these widely separated binaries, the stellar components evolve independently as long as both remain on the main-sequence, but they interact considerably during late stages of evolution. This particular evolutionary aspect uniquely distinguishes symbiotics from other classes of interacting binaries. The relevant interaction processes include mass expulsion from a common envelope between the stars, accretion disk formation, outbursts, and mass outflow that can lead to the formation of jetlike structures (e.g., CH Cyg, R Aqr). There is still much to learn about the nature of symbiotic systems due to the difficulty of directly observing the secondary star.

At visual wavelengths, symbiotic stars are characterized by the presence of absorption features and continua appropriate

[^0]for a late-type M star, often a Mira or other long-period variable. Nebular emission lines, including both forbidden and Balmer line emission, suggest the presence of a high-excitation source (Boyarchuk 1975).

The near and far-UV afford an opportunity to directly probe the temporal behavior of high-excitation emission lines in symbiotics because the luminous M star, which dominates the integrated visible and infrared light, makes essentially no contribution at UV wavelengths. Thus, the far-UV provides a means of directly probing the high excitation source in these systems. The UV spectra of symbiotic stars suggest an enormous range of excitation that extends from low-temperature species such as O I $_{\text {I }} \lambda \lambda 1302-1306$, C II $\lambda \lambda 1334,1335$, Si II $\lambda \lambda 1806,1816$, and Mg II $\lambda \lambda 2795,2802$ to strong resonance emission lines such as $\mathrm{N} v \lambda \lambda 1238,1242$, C iv $\lambda \lambda 1548,1550$, as well as other high-ionization lines such as He if $\lambda 1640$ that are photoexcited by the EUV continuum radiation that corresponds to a source with a $T_{\text {eff }}$ of at least $50,000 \mathrm{~K}$ to $100,000 \mathrm{~K}$. Moreover, the intersystem lines of O IV] $\left.\left.\lambda \lambda 1397-1407, \mathrm{~N}_{\text {IV }}\right] \lambda 1487, \mathrm{O}_{\text {III }}\right] \lambda \lambda$ $1660,1666, \mathrm{~N}$ III] $\lambda \lambda 1747-1753, \mathrm{Si}$ III] $\lambda 1892$ and C III] $\lambda \lambda$ 1907,1909 reflect the circumstellar nebular conditions of symbiotic stars.

Allen (1982) has defined two categories of symbiotic stars based upon IR photometry. Type S stars have blackbody continuum emission in the $K$-band, while type D symbiotics exhibit thermal silicate emission from dust. Most known symbiotics ( $\sim 110$ out of 140 ) are S types, and about $30(20 \%)$ are classified as type D.

S-type systems contain an M giant and often exhibit a stellar blackbody continuum flux distribution in the far-UV. In the 1200-2000 A wavelength range of the IUE SWP camera this flux is generally appropriate to a $T_{\text {eff }} \gtrsim 50,000 \mathrm{~K}$ star (Penston \& Allen 1985), which is in agreement with the presence of the $\mathrm{N} \mathrm{v}, \mathrm{C}$ iv, and He il emission lines. The presence of strong silicate emission at 10 to $20 \mu \mathrm{~m}$ seems to correlate with the presence of long-period variables, e.g., Miras, in D-type symbi-
otics (Allen 1982; Kafatos, Michalitsianos, \& Feibelman 1982). The D-type symbiotics all have a similar UV continuum flux distribution (Penston et al. 1983) that rises with increasing wavelength in the 2000-3200 $\AA$ wavelength range of the IUE LWR/LWP cameras (see Kafatos, Michalitsianos, \& Feibelman 1982). Since no hot secondary star has been directly observed in these systems, some secondary stars may be buried in the nebular material. Thermal IR emission, presumably from dust, may be associated with extensive mass loss from Mira winds.

The six known symbiotic stars positively identified with soft X-ray emission are: V1016 Cyg, RR Tel, HM Sge (Allen 1981), AG Dra, CH Cyg (Anderson et al. 1981) and R Aqr (Viotti et al. 1987). Four of these are D type. Accretion in the D-type systems may occur at rates as high as $10^{-5}$ or $10^{-4} M_{\odot} \mathrm{yr}^{-1}$. These rates are higher than for the two S-type systems (AG Dra and CH Cyg), in which an inner accretion region with $T \sim 10^{6}$ K can explain the observed soft X-ray emission. Although it contains an M giant, the S-type symbiotic CH Cyg is a strong X-ray source. The other S-type, AG Dra, contains a K giant of ambivalent spectral class.

## 2. DESCRIPTION OF THE ATLAS

This atlas contains samples and analysis of the far-UV spectra of 32 symbiotic stars made with the IUE SWP camera between 1978-1988. We have selected the spectra with the best signal-to-noise ratio from those presently available in the IUE archive. Tracings of the spectra of 32 symbiotics are reproduced in Figures 1-32. In all, 394 low-resolution spectra with $\Delta \lambda \sim 6 \AA$ limiting resolution were examined, all in the $1200-$ $2000 \AA$ range. Part 2 of the atlas will present the spectra of symbiotics observed in the LWR/LWP wavelength range of 1900-3200 $\AA$. A complete catalog of all 42 symbiotic stars that have been observed by $I U E$ was not possible because many of the spectra were either significantly underexposed or saturated. This atlas complements various other catalogs (see Allen 1984; Sahade, Brandi, \& Fontenla 1984; Kenyon 1986).

Table 1 lists the observational parameters for each object: right ascension, declination, date and time, SWP number, and, if applicable, orbital phase. A final column indicates whether an eruptive object was in the active or quiescent stage. The absolute line intensities for the most prominent emission lines present in the SWP wavelength range are shown in Table 2. Several of the symbiotic stars in the Atlas have far-UV spectra that show large temporal flux variations. These include both systems with phase-dependent occultation effects in known eclipsing binaries with well-determined ephemerides and outburst systems in active and in quiescent states.

General properties of the stars in the atlas, such as spectral type, radio flux, Mira period, etc., are given in Table 3. Finally, Table 4 compares the spectral features such as intercombination line strength, resonance line strength, and continuum flux distribution of the symbiotic stars.

## 3. OBSERVATIONS AND ANALYSIS

The IUE spectra presented in the atlas were analyzed and produced with data analysis routines written in IDL available at the IUE Regional Data Analysis Facility (RDAF) at the NASA Goddard Space Flight Center. Since the IUE spectra
presented in this atlas were collected at different epochs, we have reprocessed all of the IUE SWP spectra with the latest IUESIPS data reduction routines. This insures, as much as possible, that all spectra for each object have been analyzed using the same calibration and extraction procedures.

For objects that exhibit strong UV flux variations, i.e., eclipsing systems and systems with active and quiescent states, we have given the absolute fluxes at the phases specified in Table 1. For the faintest stars (BI Cru, LMC Anon, He 2-38), spectra have been co-added to increase the signal-to-noise ratio. The spectra in this atlas have not been corrected for interstellar extinction, because the precise nature and value of the circumstellar extinction component present is quite uncertain. However, accepted values for $E_{B-V}$ are listed in Table 3.

In systems where the UV continuum is well exposed, absolute emission-line fluxes are taken relative to the continuum base. Otherwise, in weak continuum objects the absolute fluxes are taken above zero. The absolute emission-line fluxes found in Table 2 are subject to IUE uncertainties of about $20 \%$ for the strongest lines. The weaker lines are more affected by calibration errors and poor signal-to-noise ratio. In addition, there has been a mean sensitivity degradation in the SWP camera of about $1 \%$ per year (Bohlin \& Grillmair 1988). Combining these effects, we estimate a maximum uncertainty in the comparison of absolute IUE line fluxes of approximately $30 \%$ over the period from 1978 to 1988.

## 4. DISCUSSION OF INDIVIDUAL STARS

In this section we provide brief descriptions of the far-UV spectra and the most important properties of the symbiotic stars in this atlas. Further information about each of these objects is provided in the accompanying tables.

### 4.1. EG Andromedae

We present in Figure 1 UV spectra of EG And both in and out of eclipse during the years 1978-1984. The spectra shown illustrate its behavior at visual minimum and maximum phases (Chochol et al. 1987). Principal among the emission
 C III]. The continuum flux distribution clearly increases toward shorter wavelengths out of eclipse yet vanishes when the star is near minimum phase. This could indicate that the hot star is being eclipsed by the extended atmosphere of the cool primary (see Fig. 1). Several emission lines (e.g., $N v \lambda \lambda$ 1238,1242 , O i $\lambda \lambda 1302-1306$, Не iI $\lambda 1640$, and $\mathrm{N}_{\text {iv }} \lambda 1718$ ) are very weak at minimum phase. Using a UV light curve, on the other hand, Munari et al. (1988) explain these variations as a reflection effect rather than eclipse-like variations of the star. We suggest that these variations could also occur if the high-excitation lines $N$ v $\lambda \lambda 1238,1242$ and $\mathrm{He}_{\text {II }} \lambda 1640$ are formed close to the secondary star, in which a high-excitation, compact line-emitting region is more susceptible to eclipses.

## 4.2. $A X$ Persei

Figure 2 shows UV spectra of AX Per corresponding to several orbital phases in the visible. For this, we used the optical ephemeris determined by Kenyon (1982). The UV continuum flux distribution is flat during optical minimum but increases

Notes.-Flux units are $10^{-14} \mathrm{ergs} \mathrm{cm}^{-2} \mathrm{~s}^{-1} \AA^{-1}$. Measured wavelengths are averages. Laboratory wavelengths are in italics in the header. Measured wavelengths, in italics with each star, are averages. Asterisk (*) indicates a saturated feature.

General Properties of the Symbiotic Stars in this Atlas Observed with IUE

| RX Pup | 5 | C IV, He II strong | C III] strong |  | flat,, red | intersystem emission decreasing since 1980-82 |
| He2-38 | 6 | C IV strong | O III], C III] strong | noisy |  | spectra weak |
| SY Mus | 7 | 2 x less at $=0.0$; C IV, He II strong | weak in UV | drops at min. |  | N V and C IV very prominent out of eclipse |
| BI Cru | 8 | N V present | O III], Si III] strong | noisy |  | noisy even when co-added |
| RW Hya | 9 | many broad, high ionization lines seen | forbidden doubly ionized lines weak | low on one obs. | , blue | possibly eclipsing, in compact high density nebula |
| He2-106 | 10 | C IV, He II seen | O III], C III] seen | > $1600 \AA$, weak |  | noisy, even when co-added |
| Hen 1092 | 11 | C IV, He II equally strong | very weak > $1700 \AA$ |  | flat | very dense nebula? |
| T CrB | 12 | strong when continuum strong | strong when continuum strong | varies | flat | substantial variation in continuum and line flux |
| AG Dra | 13 | He II stronger than C IV in both states | weak in both outburst \& quiescent states | very strong at outburst | , blue at outburst | 15 year activity cycle for outbursts - anomalous outburst in 1985, 86 |
| HK Sco | 14 | N V, C IV, He II observed | weak in UV | noisy | flat | 1982 C IV, He II > 1981 C IV, He II |
| CL Sco | 15 | C IV predominates | O III], Si III], C III] unusually strong | noisy | , red | low density, photoionization region? |
| H1-36 Arae | 16 | C IV, He II broad | N III], C III] broad | none |  | broad emission lines |
| Y CrA | 17 | strong, narrow He II | narrow | weak | flat | main sequence, accreting star ? |
| YY Her | 18 | all strong | O IV], N IV], O III] strong; weak > $1700 \AA$ | constant | flat | much weaker in 12/81 and in 5/80 |
| AS 296 | 19 | $\checkmark$ after outburst | , after outburst, especially > $1600 \AA$ | noisy, weak | $\sim$ flat | outburst in 1988 June |
| AS 295B | 20 | C IV, He II broad | broad | none |  | only one IUE spectrum available |

TABLE 4-Continued

| Star | Fig. | Principal Resonance Lines | Principal Intersystem Lines | Continuum Flux | Continuum Shape | Comments |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| AR Pav | 21 | stronger by 2 x out of eclipse | weaker during eclipse | weak in eclipse | , red non-eclipse | effects of eclipse are very noticeable |
| V443 Her | 22 | N V, C IV strong | O IV], N III], Si III], C III] strong | strong | flat | 11/80 spectrum $\sim 1.25 x$ strength of $5 / 80$ |
| BP Cyg | 23 | N V, O I very weak, except at visual maximum | prominent; weaker during eclipse | very strong | , blue at max. flat at min. | possibly eclipsing; emission in '86-'88 > '79-'80 |
| CH Cyg | 24 | strength varies with system state | strength varies with state of the system | varies erratically | $\begin{aligned} & \text { often flat; } \\ & \text {, red } \end{aligned}$ | several active phases; opaque, circumstellar, iron shell |
| HM Sge | 25 | all lines intense | many intense lines | almost none | flat | variable emission intensity |
| CI Cyg | 26 | stronger during ' 82 eclipse than ' 80 | brighter during ' 80 eclipse than ' 82 | weak; 0 at min. | flat | excitations vary from one eclipse to another |
| V1016 Cyg | 27 | very strong, $2 x$ at UV maximum | very strong, 1.5 x at UV maximum | weak | flat | [ Ne IV], [ Ne V ] present |
| RR Tel | 28 | strong, , from '78 to '87 | strong, gradually decreasing | very weak | flat | consistent with a slow nova on the decline |
| IHBV 475 | 29 | C IV, He II, strongest at visual max. | somewhat weak, vary with visual phase | very weak | flat | consistent with an eclipsing binary |
| AG Peg | 30 | strong | N IV] exceptionally strong, weaker > 1700 A | strong | , blue | one of the brightest; has a dense nebular region |
| Z And | 31 | strong, He II much stronger in quiesence | strong, 2-3x as much during outburst | outburst: strong quies.: moderate | $\begin{aligned} & \text { > red } \\ & \text { flat } \end{aligned}$ | relative strength of intersystem lines greater at outburst, implying material from cool component being photoionized |
| R Aqr | 32 | N V weak, C IV dominates | C III] dominates, most are present | strong | flat | has a jet seen in both radio and UV |

Notes.—Dagger ( $\dagger$ ) indicates N v $\lambda \lambda 1238,1240$; C iv $\lambda \lambda 1548$; 1550; He II $\lambda 1640$. Double dagger ( $\ddagger$ ) indicates O IV] $\lambda \lambda 1397$, 1407; N IV] $\lambda 1487$; O III] $\lambda \lambda 1660$, 1666; N III] $\lambda \lambda 1747$, 1753; Si III] $\lambda 1892$; C III] $\lambda \lambda$ 1906, 1909. The arrow pointing up ( $\nearrow$ ) means "increasing toward," and the arrow pointing down ( $\searrow$ ) means "decreasing toward."

Fig. 1.-Low-resolution IUE spectra of EG Andromedae obtained in the SWP $\lambda \lambda 1200-2000$ wavelength region. The spectra were taken at orbital phases determined by Chochol et al. (1987) with $\min (U B V)=$ JD $2,446,336.7+474.0^{\mathrm{d}} E$.

FIG. 2.-Low-resolution SWP spectra of the symbiotic star AX Persei. Orbital phases were found from an ephemeris by Kenyon (1982) using min (pg) $=$ $2,436,679.4+681.6^{\mathrm{d}} E$. The UV continuum increases toward longer wavelength when the star is near a maximum.
near maximum, showing a slight rise toward longer wavelengths. UV emission line intensities vary by factors of $2-3$ from optical minimum to maximum. C iv $\lambda \lambda 1548,1550$ is the most prominent emission line in the spectra. The strength of the $\left.\mathrm{O}_{\text {III }}\right] \lambda \lambda 1660,1666$ and $\left.\mathrm{C}_{\text {III }}\right] \lambda \lambda 1907,1909$ emission lines seen (Fig. 2) steadily decrease, while the He iI $\lambda 1640$ emission line increases, consistent with progressively higher density regions coming into view during this orbital phase. The UV flux distribution of AX Per is similar to that of CI Cyg because they are both relatively flat (independent of wavelength) and exhibit intense narrow emission lines (Kenyon 1986).

### 4.3. LMC Anon

Three UV spectra of LMC Anon have been co-added (Fig. 3) to increase the signal-to-noise ratio. The UV continuum is very weak but shows a slight increase toward shorter wavelengths consistent with hot, stellar blackbody emission. $\mathrm{N} v \lambda \lambda$ $\left.1238,1242, \mathrm{~N}_{\text {IV }}\right] \lambda 1487$ and $\mathrm{N}_{\text {III }} \lambda \lambda 1747-1753$ are the strongest emission lines present in the spectrum (Table 3). High ionization lines of C IV and He II, which are present in most symbiotics, are not nearly as intense compared with $\mathrm{N} v$ and

Fig. 3.-Three co-added spectra of LMC Anon are shown. These spectra are not well exposed. $\mathrm{N} v \lambda \lambda 1238,1240, \mathrm{~N}$ IV] $\lambda 1487$, and N iII] $\lambda \lambda$ 1747-1753 are particularly strong.

Fig. 4.-This spectrum of LMC S63, obtained in 1982 March, exhibits a UV continuum increasing toward shorter wavelengths, characteristic of a hot star with $T_{\text {eff }}>25,000 \mathrm{~K}$.

N IV], which are about 2-3 times stronger than the $\mathrm{He}_{\mathrm{II}}$ and C iv lines, respectively. The presence of relatively weak carbon and strong nitrogen emission lines suggests evidence of CNO processing (Kafatos et al. 1983).

### 4.4. LMC S63

The UV spectrum of LMC S63 shown in Figure 4 exhibits a continuum flux distribution which increases steeply toward shorter wavelengths and contains many allowed and semiforbidden emission lines (e.g., N v, N IV], C iv, He iI, O iII], N iII],

Fig. 5.-Low-resolution IUE spectra of RX Puppis, covering 1980 September to 1986 May

Fig. 6.-Two low-resolution SWP spectra of He 2-38 have been coadded to increase the signal-to-noise ratio. The UV continuum is very weak.
yon \& Bateson (1984) was used to determine the phase for each spectrum in Figure 7. At minimum ( $\Phi=0.0$ ), the continuum drops noticeably, and the emission line strengths decrease by factors of $3-4$. N v, C iv, and He iI are very prominent out of eclipse at $\Phi \sim 0.5( \pm 0.1)$, indicating the presence of the hot

star. C iv $\lambda \lambda 1548,1550$ and $\mathrm{He}_{\text {II }} \lambda 1640$ are the most intense lines in all the IUE spectra of SY Mus. The intersystem lines of $\mathrm{O}_{\text {III], }} \mathrm{NiII}^{\mathrm{II}}$, Si III], C III] are generally weak, suggesting high densities $n_{e} \geq 10^{8} \mathrm{~cm}^{-3}$ (Michalitsianos et al. 1982).

### 4.8. BI Crucis

Two SWP spectra of BI Crucis (Fig. 8) were co-added for noise reduction. Even so, the UV spectrum of this symbiotic is characterized by a noisy continuum, if any, with a UV flux distribution which increases toward shorter wavelengths. Only a few emission lines can be clearly identified in the enhanced spectrum.

### 4.9. RW Hya

The SWP spectra of RW Hya in Figure 9, obtained between 1979 and 1987, exhibit a UV continuum flux distribution which increases noticeably toward shorter wavelengths, consistent with hot stellar blackbody emission. The presence, in some cases, of many broad, high-ionization emission lines (e.g., Si iv + O iv] $\lambda \lambda$ 1393-1407, N iv] $\lambda 1487$, C iv $\lambda \lambda$ 1548,1550 , He II $\lambda 1640$, and $\mathrm{O}_{\mathrm{III}} \lambda \lambda 1660,1666$ ) suggests a hot photoionized nebular region. The emission-line intensities are 2-3 times smaller in SWP 31038 than those found in the

FIG. 7.-Low-resolution IUE far-UV spectra of the symbiotic star SY Muscae. These spectra exhibit a nearly flat UV continuum near visual minimum $(\Phi=0.0 \pm 0.1)$. All orbital phases were determined from the ephemeris $\min (V)=\mathrm{JD} 2,435,175.7+627.0^{\mathrm{d}} E$ (Kenyon \& Bateson 1984).

Fig. 8.-The low-resolution IUE spectrum of BI Crucis. Two spectra of BI Cru have been co-added to increase the signal-to-noise ratio. Even so, the UV continuum is still noisy. X indicates a cosmic-ray hit.

preceding 1985 June (SWP 26220) spectrum. The lack of continuum and the significant decline in emission-line strength suggests that RW Hya is possibly an eclipsing system. The weakness of forbidden lines N III] $\lambda \lambda$ 1747-1753, Si III] $\lambda 1892$, and C III] $\lambda \lambda 1907,1909$ implies that the compact nebula in which both the primary and secondary stars are embedded has particularly high densities, in agreement with Kafatos, Michalitsianos, \& Hobbs (1980). Further observations should be made to determine if RW Hya is an eclipsing system.

### 4.10. He 2-106

The UV spectrum of He 2-106 (Fig. 10) is generally noisy, but UV continuum emission is present longward of $1600 \AA$. C iv $\lambda \lambda 1548,1550$, $\mathrm{He}_{\text {II }} \lambda 1640$, $\mathrm{O}_{\text {III] }} \lambda \lambda 1660,1666$ and C III] $\lambda \lambda 1907,1909$ are the most prominent emission lines in the SWP range. Gutierrez-Moreno, Moreno, \& Cortes (1986) suggest that He 2-106 is an optically thick D-type object that exhibits an IR excess due to circumstellar dust.

FIG. 9.-Low-resolution SWP spectra of RW Hydrae obtained between 1979 January and 1987 May. The majority of spectra have a far-UV continuum which increases toward shorter wavelengths, consistent with a hot subdwarf.

Fig. 10.-An SWP low-resolution spectrum of the symbiotic star He 2-106 taken in 1986 July. The UV continuum is underexposed and noisy, with a few narrow emission lines of C IV, He II, and C III]. X denotes a cosmic ray hit.

### 4.11. Hen 1092

The IUE spectrum of Hen 1092 (Fig. 11), taken in 1980 March, has a relatively flat continuum flux distribution with both permitted and intersystem emission lines of $\mathrm{N} \mathrm{v}, \mathrm{O}$ Iv], $\mathrm{N}_{\text {iv] }}$, C iv, He iI, O iII]. He iI $\lambda 1640$ having comparable intensity to C iv $\lambda \lambda 1548,1550$ suggests that the high-excitation permitted line forming region is quite hot, probably in the range $65,000 \leq T_{\text {hot }} \leq 100,000 \mathrm{~K}$. The weak semiforbidden lines beyond $1700 \AA$ of $N$ III] $\lambda \lambda$ 1747-1753, Si III] $\lambda 1892$, and C iII] $\lambda \lambda 1907,1909$ could indicate a very dense nebula where $n_{e} \geq 10^{8} \mathrm{~cm}^{-3}$.

### 4.12. T Coronae Borealis

Figure 12 displays the variable UV continuum of TrB at several stages. Emission lines are more pronounced when the

UV continuum flux is strong and become weak when the continuum decreases. With increasing UV continuum flux, $\mathrm{N} v$, C iv, He II, O III], Si III], and C III] become more prominent, the brightest line being C iv $\lambda \lambda 1548,1550$. Spectra taken in 1979 (SWP 3815 and SWP 5804) exhibit vastly different continuum levels compared with more recent spectra. The two spectra taken in 1986 (SWP 27556 and SWP 28715) suggest large variations in the continuum level. These continuum variations with timescales of about 1 yr could be associated with accretion. Kenyon \& Garcia (1986) suggest that an accreting main-sequence star, rather than a white dwarf, that gains $\sim 10^{-6} M_{\odot}$ $\mathrm{yr}^{-1}$ is the hot companion. Fluctuations associated with an optically thin disk may be responsible for the substantial variations in the UV continuum and emission-line flux observed.

### 4.13. AG Draconis

The IUE spectra taken of AG Dra are characterized by either a strong continuum rising toward shorter wavelengths in outburst or a flat, weak continuum in quiescence. Both phases are associated with intense permitted emission lines (e.g., N v , C iv, $\mathrm{He}_{\mathrm{II}}$ ), and weak intersystem emission lines (e.g., N iII], Si III], C III]) (Fig. 13). Emission-line intensities increase by a factor of 3 to 6 during active phases, compared with quiescence. The continuum level was considerably higher in the 1980/1981 outburst (SWP 11002, SWP 15709) than in the 1985/1986 outburst (SWP 27542). N v, C iv, and He it are the strongest emission lines in both active and quiescent states, while $\mathrm{Si}_{\mathrm{III}}$ ] and C III] are always weak or absent, consistent with a high-density nebula ( $10^{10} \leq n_{e} \leq 10^{11} \mathrm{~cm}^{-3}$ ) (Kafatos, Meier, \& Martin 1993).

### 4.14. HK Scorpii

One of the least studied symbiotics, HK Sco exhibits a relatively weak UV continuum that is relatively flat and noisy. However, N v $\lambda \lambda 1238,1242$, C iv $\lambda \lambda 1548,1550$ and He II $\lambda 1640$ are both present suggesting a hot source $65,000 \leq T_{\text {hot }} \leq$

## WAVELENGTH (A)

Fig. 11.-The far-UV spectrum of Hen 1092 obtained in 1980 March. This star has a flat continuum and strong emission lines of C iv $\lambda \lambda 1548,1550$ and He iI $\lambda 1640$.

Fig. 12.-IUE low-resolution spectra of T Coronae Borealis. Most of the UV spectra shown exhibit a strong and variable continuum with many broad emission lines.
$100,000 \mathrm{~K}$ in the line-forming region; the conspicuous weakness of semiforbidden lines also suggests the densities are $n_{e} \leq$ $10^{10} \mathrm{~cm}^{-3}$. A decrease in continuum and emission line intensity is evident in the spectra shown in Fig. 14 obtained in 1981 March and 1982 February. Between these two observations the C iv flux decreased by a factor of 4 and He il by a factor of 2 .

### 4.15. CL Scorpii

Although the spectrum of CL Sco (Fig. 15) is rather noisy, the continuum rise with increasing wavelength is evident. The semiforbidden lines of $\mathrm{O}_{\text {III }}$, Si III], C III], as well as C IV are the strongest emission lines in the spectrum, while $\mathrm{N} \mathrm{v} ,\mathrm{C} \mathrm{iI} ,\mathrm{O} \mathrm{IV]}$, $\mathrm{N}_{\text {IV] }}$ and others shortward of $1500 \AA$ are weak. The strong intersystem lines are evidence of a low-density photoionized region, i.e., $10^{4} \leq n_{e} \leq 10^{8} \mathrm{~cm}^{-3}$.

### 4.16. H1-36 Arae

In this UV spectrum of H1-36 Arae (Fig. 16), the most prominent lines are the broad emission profiles of C IV $\lambda \lambda$ 1548,1550 , He II $\left.\lambda 1640, \mathrm{~N}_{\text {III }}\right] \lambda 1747-1753$ and C III] $\lambda \lambda$ 1907,1909. The continuum is underexposed.

### 4.17. $Y C r A$

The far-UV spectrum of Y CrA in SWP 6820 (Fig. 17) is relatively weak. This early $I U E$ exposure shows a low, flat con-
tinuum and several allowed and intercombination lines of N v ,

### 4.18. YY Herculis

The far-UV spectrum of YY Her is dominated by the emission lines of $\mathrm{N} v, \mathrm{~N}_{\mathrm{IV}}$ ], C IV, He II , and O III] superimposed on a flat continuum (Fig. 18). Many semiforbidden lines (i.e. $\mathrm{N}_{\text {IIII }}$, Si III], and C III]) in the spectrum longward of $1700 \AA$ are very weak. The emission line intensities decreased generally by a factor of 2 to 3 between 1980 May and 1981 December. Over this 1.5 yr period, the intensity in N v and O I decreased by factors of 6 and 4, respectively, consistent with YY Her being an eclipsing system. However, the continuum flux did not decrease together with the emission line fluxes, except below $1400 \AA$, suggesting the regions in which free-free and freebound emission originate are more extended than the line forming regions.

$$
\text { 4.19. } A S 296
$$

The IUE spectra of AS 296 are noisy and exhibit a weak continuum. In the spectra shown here, C IV $\lambda \lambda 1548,1550$ is the only prominent high-excitation line. The first two spectra in Figure 19 were taken in 1982 February (SWP 16380) and 1982 November (SWP 18389). Six years later, spectra were obtained 3 months prior to the 1988 March outburst (SWP 33047) and 5 months following that outburst (SWP 34725)

FlG. 13.-Low-resolution SWP spectra of AG Draconis. These spectra are representative of the system in active and quiescent states. Note the variations in the UV continuum between activity and quiescence.

## SWP 13582 <br> 

Fig. 14.-Low-resolution IUE spectra of the symbiotic star HK Scorpii. The spectra exhibit strong emission lines of C IV and He II superposed on a weak UV continuum.

Fig. 15.-A low-resolution SWP spectrum of CL Scorpii taken in 1980 July. Weak UV continuum appears to rise with increasing wavelength.

FIG. 16.-This low-resolution SWP spectrum of H1-36 Arae was obtained in 1979 October. The spectrum is not well exposed, but broad emission lines of C IV and C III] are detected.

FIG. 17.-Low-resolution spectrum of Y CrA obtained in 1979 October. Y CrA exhibits weak emission lines that are superposed on a flat UV continuum.

Fig. 18.-Low-resolution IUE spectra of YY Herculis. The spectra show permitted and intersystem emission lines on a relatively flat UV continuum flux distribution.

Fig. 19.-Low-resolution SWP spectra of the symbiotic star AS 296. All spectra are underexposed. C iv $\lambda \lambda 1548,1550$ is the most prominent emission line. X indicates a cosmic ray hit.
(Munari 1988). The latter of these suggests an increase in the continuum flux longward of $1600 \AA$ and an increase in the intensity of many of the intersystem lines (e.g., $\mathrm{O}_{\mathrm{III}}$ ], Si III], and C III]). This increase in the intersystem line strength, coupled with a decrease in the principal permitted lines of C Iv and He il could indicate that the atmosphere of the $M$ giant has been photoionized by the hot star.

$$
\text { 4.20. } A S 295 B
$$

The UV spectrum of AS 295B in Figure 20 shows broad emission lines of C iv $\lambda \lambda 1548,1550$ and He iI $\lambda 1640$. As with H1-36 Arae, underexposure has left no trace of a continuum.

### 4.21. AR Pavonis

$I U E$ ultraviolet spectra of AR Pav in and out of eclipse (Fig. 21), indicate that the UV continuum and emission lines strongly depend on the orbit phase. When AR Pav is out of eclipse (SWP 5829, SWP 13956) (Andrews 1974) the continuum flux rises noticeably with increasing wavelength and the emission lines tend to be stronger; C iv $\lambda \lambda 1548,1550$ and He it $\lambda 1640$ fluxes also increase by a factor of 2 . During a minimum visual phase there is an overall decrease in continuum and emission line intensities expected because the hot star is partly occulted. This decrease can be seen in SWP 10510, SWP 16857, and SWP 17070, which show the presence of continuum and emission lines around phase $\Phi=0.0( \pm 0.1)$.

### 4.22. V443 Herculis

The far-UV spectra of V443 Her shown in Figure 22 indicate a relatively strong and flat continuum with many intense emission lines superposed. Both spectra show strong Si iv, O iv], N iv], C iv, He II, and $\mathrm{O}_{\text {III] }}$ emission. The emission-line intensities increased by about $15 \%$ during the 6 month period from 1980 May (SWP 9122) to 1980 November (SWP 10439).

### 4.23. BF Cygni

The UV spectra of BF Cyg (Fig. 23) indicate a strong UV continuum which increases toward shorter wavelengths, except near visual minimum, $\Phi=0.0$, when the hot star is in eclipse. The UV continuum flux distribution varies with the photometric ephemeris determined by Mikolajewska (1987), consistent with an occultation of the hot companion star. The spectra at minimum show a flat continuum with weak Nv and O I (SWP 13477 and SWP 30924), while spectra near maximum exhibit a strong UV continuum and emission lines. Many of the intersystem lines are particularly prominent, such as $\mathrm{O}_{\text {III] }}, \mathrm{N}$ III], Si III], and C III]. The $\mathrm{N} v$ and O i permitted

FIG. 20.-Low-resolution SWP observation of AS 295B taken in 1979 August. This spectrum exhibits broad emission lines from C IV and He II, superposed on a underexposed UV continuum.

FIG. 21.-Low-resolution $I U E$ spectra of AR Pavonis obtained in and out of eclipse. Orbital phases were determined from Andrews $(1974)$ min $(V)=$ $2,420,330+604.4^{\mathrm{d}} E$. Notice that the strength of the UV continuum flux distribution exhibits orbital phase dependence.

Fig. 22.-Low-resolution SWP spectra of V443 Herculis obtained in 1980. Both spectra exhibit a moderately strong UV continuum accompanied with many intense emission lines. C iv $\lambda \lambda 1548,1550$ is particularly strong.

Fig. 23.-Low resolution IUE spectra of the symbiotic star BF Cygni. Near minimum the UV continuum flux decreases noticeably. Orbital phases were calculated using the ephemeris $\min (\mathrm{pg})=2,415,058+756.8^{\mathrm{d}} E$ (Mikolajewska 1987).

Fig. 24.-Low-resolution spectra of CH Cyg obtained from 1979 December to 1987 January. The continuum is highly variable in flux level and wavelength distribution. SWP 22056 was taken following outburst, when the UV continuum was heavily blanketed by Fe in absorption.
that is accompanied by weak emission features, suggesting that the system is in a low-excitation, quiescent state. Line blanketing from $\mathrm{Fe}_{\mathrm{II}}$ is not apparent.

### 4.25. HM Sagittae

The $I U E$ spectra of the D-type symbiotic star HM Sge shown in Figure 25 are characterized by a very weak, flat continuum with many intense emission lines of $\mathrm{Nv}, \mathrm{N}$ iv], C iv, $\mathrm{He}_{\text {II, }} \mathrm{O}_{\mathrm{III}}$, Si III], C III]. These spectra show that the emissionline intensities decreased slightly between 1980 August (SWP 9898 ) and 1981 August (SWP 14756) but increased by about a factor of 2 through 1982 April (SWP 16752) to 1986 August (SWP 28896). This activity was followed by a decrease from 1986 August to 1987 April.

### 4.26. CI Cygni

The far-UV spectra in Figure 26 show CI Cyg in and out of eclipse in 1980 and 1982. There are many prominent emission lines (e.g., N IV], C iv, He II, O III], and C III]) superposed on a flat continuum which disappears at visual minimum phase (Aller 1954). During the 1982 eclipse, many resonance lines such as N v and He il were stronger than during the 1980 eclipse. Many of the intersystem lines (e.g., $\mathrm{O}_{\mathrm{III}}$ ], N III], C III]) were much brighter during the 1980 eclipse, suggesting the hot source interacted more with the M giant atmosphere than in 1982 during the earlier eclipse phase.

### 4.27. V1016 Cygni

The UV spectrum of V1016 Cyg displays many intense
 Si III], and C III]) superposed on a weak continuum. As shown in Figure 27, the emission lines [ Ne v ] $\lambda 1574$ and [ Ne Iv] $\lambda 1601$, usually weak in most symbiotics, are very strong in the UV spectrum of V1016 Cyg. All orbital phases were determined using the UV ephemeris of Nussbaumer \& Schmid (1988). During a UV maximum, $\Phi=0.5( \pm 0.1)$, the emission lines increase in strength by a factor of about 2 . The strongest emission spectra reproduced are SWP 5611 and SWP 9878, both of which are near UV maximum. Whitelock (1987) finds that the UV continuum is strongly reduced by both interstellar and circumstellar reddening.

### 4.28. $R R$ Telescopii

The SWP spectra shown in Figure 28 exhibit many strong emission lines that include $\mathrm{N} v, \operatorname{Si}$ iv, O iv], N iv], C iv, He il, $\mathrm{O}_{\text {III] }}$, and $\mathrm{C}_{\text {IIII }}$, reflecting a broad range of ionization energies. There are many strong permitted lines from the spectra of Nv , C iv, and He il that provide evidence of a hot star $T_{\text {hot }} \geq 10^{5} \mathrm{~K}$. The emission-line intensities have varied by a factor of 2 or 3 between the 1978 and 1987 IUE observations, consistent with the behavior of slow novae which exhibit a slow decline following outburst.

### 4.29. HBV 475

The far-UV spectrum of HBV 475 (or V1329 Cyg) exhibits very weak UV continuum flux and a wide assortment of permitted and intersystem lines that includes $\mathrm{N} v, \mathrm{Si}$ iv, O iv],

Fig. 25.-Low-resolution IUE spectra of HM Sagittae. This system exhibits many intense permitted and intersystem emission lines that are superposed on a flat UV continuum. C IV, He II, and C III] produce the strongest emission lines in the spectra.

Fig. 26.-Low-resolution spectra of CI Cygni taken between 1979 June and 1983 August. These spectra were obtained before and after eclipses that occurred in 1980 July and 1982 November. During a minimum phase, $\Phi=0.0( \pm 0.1)$, the UV continuum disappears, while at maximum, $\Phi=0.5( \pm 0.1)$, the continuum is slightly elevated. Orbital phases for each spectrum were found from Aller (1954) $\min (V)=\mathrm{JD} 2,411,902+855 \mathrm{~d} 25$.

FIG. 27.-Low-resolution spectra of V1016 Cygni obtained between 1978 August and 1987 November. V1016 Cygni exhibits many broad, permitted, and intersystem emission lines. Orbital phases were determined from Nussbaumer \& Schmid (1988) min(UV) $=$ JD $2,444,101+3470^{\mathrm{d}} E$.

Fig. 28.-Low-resolution SWP spectrum of RR Telescopii. This spectrum contains numerous high-excitation emission lines, the most intense are $\mathbf{N} \mathbf{v}$, C iv and He iI. The UV continuum flux is relatively flat and independent of wavelength.

FIG. 29.-Low-resolution IUE spectra of HBV 475 (=V1329 Cyg) obtained between 1980 August to 1988 September. Emission line intensities increase near maxima $\Phi=0.5( \pm 0.1)$ and decrease near minima $\Phi=0.0( \pm 0.1)$. The orbital ephemeris min $(V)=J D 2,424,870+950{ }^{\text {d }} E$ was derived by Grygar et al. (1979).

C iv, He iI, O III], N iII], Si iII], and C iII]. The permitted lines are much stronger in absolute flux than the intersystem lines (Fig. 29). IUE spectra taken between 1980-1988 show increased emission during a visual maximum phase $\Phi=0.5$ ( $\pm 0.1$ ) and a subsequent decrease in activity during a visual minimum $\Phi=0.0( \pm 0.1)$. Orbital phase values were calculated using the ephemeris $\min (V)=\mathrm{JD} 2,424,870+950{ }^{d} E$ (Grygar et al. 1979). There is a decrease in most emission-line intensities by a factor of 3,4 , or even greater between phase $\Phi=0.5$ $( \pm 0.1)$ and phase $\Phi=0.0( \pm 0.1)$. During minima, both the UV continuum and emission lines have decreased intensity, providing evidence of an eclipsing binary system.

### 4.30. AG Pegasi

AG Peg is one of the brightest symbiotic stars in the SWP wavelength range. The UV spectrum contains many broad intense emission lines (e.g., N v, N iv], C iv, He iI, and $\mathrm{O}_{\mathrm{III}}$ ) and a UV continuum which rises toward shorter wavelengths. In Figure 30, $N \vee \lambda \lambda 1238,1242$ has a broad base, perhaps in part due to continuum flux. The rise of continuum emission with decreasing wavelength indicates a hot component with $T_{\text {hot }} \geq$ $10^{5} \mathrm{~K}$; many authors have determined $30,000 \leq T_{\text {hot }} \leq$ 100,000 K (Gallagher et al. 1979; Keyes \& Plavec 1980; Kenyon \& Webbink 1984). N iv] $\lambda 1487$ is exceptionally strong,
while the semiforbidden line intensities of N III] $\lambda \lambda 1747-$ 1753, Si III] $\lambda 1892$, and C III] $\lambda \lambda 1907,1909$ longward of 1700 $\AA$ are weak (Fig. 30), suggesting a very dense ( $n_{e} \geq 10^{10} \mathrm{~cm}^{-3}$ ) nebular region (Keyes \& Plavec 1980; Penston \& Allen 1985).

### 4.31. $Z$ Andromedae

The far-UV spectrum of $Z$ And shows many strong intercombination and permitted emission lines that are superposed on a strong continuum which increases toward longer wavelengths during activity but is relatively flat in quiescence. Figure 31 presents eight SWP spectra taken between the years 1978 to 1988. The system was in a quiescent state between 1978 April (SWP 5809) to 1984 March (SWP 11006). An outburst occurred in 1984 March that preceded a larger outburst in 1985 September to 1986 May (SWP 26937, 27028, 27203, 27632), which was followed by a period of quiescence from 1986 June to 1988 January (SWP 32208, 32845) (Cassatella et al. 1988a,b). In outburst, there was an increase in UV absolute continuum flux that was accompanied by an increase in emission line intensities by factors of 2 or 3 for many of the intersystem lines (e.g., $\mathrm{O}_{\mathrm{III}}$ ], NiII ], $\mathrm{Si}_{\mathrm{III}}$ ] and C III]) that become more pronounced in outburst.

The continuum rises with longer wavelengths, suggesting that the hot source is photoionizing material from the cool

Fig. 30.-Low-resolution spectra of AG Pegasis. Many prominent resonance emission lines (e.g., $\mathrm{N} \mathbf{v}, \mathrm{C} \mathrm{iv}$, and He II) dominate the far-UV. Note the UV continuum flux distribution increase toward shorter wavelengths consistent with a hot subdwarf.

OUTBURST

WAVELENGTH (A)

QUIESCENT

FIG. 31.-Low-resolution spectra of $Z$ Andromedae obtained during outburst and quiescent phases. In quiescence, the spectra exhibit a flat UV continuum with strong permitted lines of C iv $\lambda \lambda 1548,1550$ and He iI $\lambda 1640$. During outburst, the intersystem emission lines dominate the spectrum, while the UV continuum rises noticeably toward longer wavelengths.

Fig. 32.-Low-resolution IUE spectra of the H II region of R Aquarii, obtained between 1979 January and 1988 January. The spectra show a few intense emission lines (e.g., C iv and C III]) and a moderately strong continuum. An X signifies a cosmic ray hit.
component. This behavior agrees with the model of Fernan-dez-Castro et al. (1988). During quiescence, the UV continuum is relatively flat and the permitted emission lines of Nv , C Iv, and $\mathrm{He}_{\mathrm{II}}$ are much brighter than during outburst, indicating that the photoionizing flux emitted by the hot star is enhanced.

### 4.32. $R$ Aquarii

R Aqr is a complex, D-type system containing a cool Mira, a hot secondary, a circumstellar envelope, and a jet of nebular
material extending $\sim 6 "$ NE of the system (Wallerstein \& Greenstein 1980). The IUE observations of the $\mathrm{H}_{\text {iI }}$ region of R Aqr shown in Figure 32 reveal moderate emission lines such as C iv $\lambda \lambda 1548,1550, \mathrm{O}_{\text {III }} \lambda \lambda 1660,1666, \mathrm{~N}_{\text {III }} \lambda \lambda 1747-1753$, Si III] $\lambda 1892$ and C III] $\lambda \lambda 1907,1909$. SWP spectra taken between 1979 January and 1988 January reveal weak to moderate emission strength, with C iv and C III] being the strongest lines. The continuum flux distribution is relatively flat as a function of wavelength over the entire SWP range.
