Received: date / Accepted: date

**Abstract** This article examines the impact of the distribution of preferences on equilibrium behavior in conflicts modeled as all-pay auctions with identity-dependent externalities. Centrists and radicals are defined using a willingness-to-pay criterion that admits preferences more general than a simple ordering on the line. Extremism, characterized by a higher per capita expenditure by radicals than centrists, may persist and generate higher aggregate expenditure by radicals, even when they are relatively small in number. Our results demonstrate the importance of the institutions of conflict in determining the role of extremism and moderation in economic, political, and social environments.

### **1 Introduction**

It is axiomatic that the nature of conflict depends on the institutions of conflict. In this paper we examine conflicts in which economic agents expend scarce resources in order to achieve their preferred outcome among a set of alternatives. If an agent secures his preferred alternative we say that the agent "wins." Otherwise, the agent "loses." In this respect the conflicts that we examine are contests as defined, say, in Konrad (2009). Our approach differs from much of the literature on contests in that agents are not indifferent to the identity of the winning agent in the event that they themselves lose.

This article investigates the impact of the distribution of preferences on equilibrium behavior in conflicts that are modeled as all-pay auctions with identity-dependent

externalities. In this context, we define centrists and radicals using a willingness-to-pay criterion that admits preferences more general than a simple ordering on the line. Extremism, characterized by a higher per capita expenditure by radicals than centrists, may persist and lead to a higher aggregate expenditure by radicals, even when they are relatively small in number. Moreover, we show that centrists may in the aggregate expend zero, even if they vastly outnumber radicals. Our results demonstrate the importance of the choice of the institutions of conflict, as modeled by the contest success function, in determining the role of extremism and moderation in economic, political, and social environments.

In much of the theoretical work on conflict to date the institutions of conflict have been black-boxed by the application of a contest success function - a function that maps the vector of agents' resource expenditures in the conflict into their respective probabilities of winning their preferred outcome. Two prominent types of contest success functions (henceforth, CSFs) employed in the literature are the "lottery" CSF (Tullock, 1980), in which the probability that an agent wins his preferred outcome equals the ratio of the agent's expenditure to the sum of all agents' expenditures, and the "auction" CSF, in which the agent with the greatest expenditure wins his preferred outcome with certainty. The lottery CSF is a popular method of modeling conflicts in which the outcome is determined not just by the respective expenditures of resources, but also a substantial random component. An auction CSF may be viewed as approximating environments in which random exogenous factors play little role in influencing the outcome of the conflict. Because of the discontinuity in the auction CSF when agents are tied for the highest expenditure, small differences in (positive) expenditure may lead to large differences in the probability of winning. That is, in contests, the auction CSF represents cutthroat competition in sunk expenditure, much the way that classical Bertrand competition is cutthroat competition in price. With the lottery CSF competition is softened by randomness in the outcome, conditional on the profile of expenditures.

Contests with identity-dependent externalities utilizing a lottery CSF have been examined by Linster (1993) and Esteban and Ray (1999). Linster (1993) demonstrates that with a constant unit cost of expenditure, pure strategy Nash equilibrium profiles of expenditures may be obtained as the solution to a nonlinear system of equations.<sup>1</sup> He analyzes two three-player environments in more detail, including a comparative statics analysis that links total conflict and social surplus to the extent of the externalities. Esteban and Ray (1999) extend Linster's (1993) model by considering groups of agents, with heterogeneous preferences across groups but homogeneous preferences within each group. Each agent has an identical strictly convex cost of expenditure function, and free-rider problems are assumed away by requiring that each group of agents acts as a single agent with the group's aggregate cost of expenditure function (and dividing the resulting expenditure equally). Hence, larger groups have lower costs. The current contribution reexamines several of the issues addressed in these papers applying the auction CSF. That is, we examine all-pay auctions with identity-dependent externalities.

---

<sup>1</sup> Linster (1993) argues that such a solution exists unless the contest is degenerate in the sense that players are indifferent to the outcome.

To the best of our knowledge, we are the first to study equilibria of the all-pay auction with identity-dependent externalities.<sup>2</sup> In this sense we provide a bridge between models of conflict such as Linster (1993) and Esteban and Ray (1999) that utilize a lottery CSF and the growing literature on winner-pay auctions with identity-dependent externalities in which agents place bids, an auction CSF is employed, but generally all bids except for the winner's are refunded. Jehiel and Moldovanu (2006) review this literature and note that the endogeneity of valuations in winner-pay auctions is the main driving force behind many new, and interesting phenomena that arise even in complete information settings.<sup>3</sup> A comprehensive treatment of the (first-price) winner-pay auction with identity-dependent externalities and complete information appears in Funk (1996).

As noted by Esteban and Ray, identity-dependent externalities can, under certain conditions, impart a natural "metric" measuring the distance between players.<sup>4</sup> If, for every  $i \in I = \{1, 2, \dots, n\}$ ,  $v_i = (v_{i1}, v_{i2}, \dots, v_{in})$  is the vector of payoffs received by player  $i$  when players  $1, 2, \dots, n$ , respectively, win their preferred option, it is natural to extend the definition of "reach" due to Siegel (2009) to account for identity-dependent externalities. More precisely, let  $r_{ij} = v_{ii} - v_{ij}$  be player  $i$ 's reach with respect to player  $j$ . That is,  $r_{ij}$  is the maximum amount that player  $i$  would be willing to expend in order to win with certainty rather than have player  $j$  win with certainty. Under the assumption of symmetry,  $r_{ij} = r_{ji}$ , players' reaches may be viewed as a distance between the preferred outcomes of players based upon the players' willingness to outbid each other to achieve their most favored outcome. Players have similar preferences over their preferred outcomes if they value the success of the other in terms similar to their own; that is, if  $r_{ij} = r_{ji}$  is small. This notion of the distance between players' preferred outcomes allows the quantification of the terms radical and centrist in terms of the set of reaches over all player pairs. Player  $i$  is a *radical* if he is an outlier in the sense that he is a player that attains the highest reach,  $\max\{r_{ij}|i, j \in I\}$ , among all player pairs, with the additional qualification that any player pair  $k, l$  attaining the same reach must include player  $i$ . A player who is not a radical is a *centrist*.

In the sections that follow we incorporate the distributions of players' preferences, as summarized by their reaches, in all-pay auctions with identity-dependent externalities to examine the behavior of centrists and radicals in Nash equilibrium. As in Esteban and Ray (1999) *extremism* refers to environments in which equilibrium expected per capita expenditures are higher for radical players than for centrists.

<sup>2</sup> Konrad (2006) examines the effect of silent shareholdings in an all-pay auction framework with complete information and finds that the social value may increase or decrease depending on the identity of the firm that holds a share in its competitor. However, Konrad does not further analyze settings in which three firms are active in equilibrium and allows only one player's valuation to be endogenous.

<sup>3</sup> For instance, in first-price winner-pay auctions, Funk (1996) and Jehiel and Moldovanu (1996) show that multiple payoff nonequivalent equilibria may arise. Jehiel and Moldovanu (1996) show that if players can commit in a pre-auction stage not to participate, both potential winners and losers may choose non-participation, despite the inability to avoid the negative externality. Janssen and Moldovanu (2004) show that revenue and efficiency may be unrelated to each other.

<sup>4</sup> Esteban and Ray (1999) do not show formally that the distance measure induced by preferences over outcomes is a metric. See section 2 for our assumptions under which there exists a semi-metric induced by players' willingness to outbid each other.

*Moderation* refers to environments in which this ranking is reversed. We analyze simple scenarios similar to those in Esteban and Ray (1999) and find that expected per capita expenditures are higher for radicals than for centrists. This advantage may lead to a higher aggregate expected expenditure by radicals, even when they are relatively small in number. In fact, centrists may in the aggregate expend zero with certainty, even when they vastly outnumber radicals. Thus, *extremism drives out moderation* if an auction rather than a lottery CSF is employed.

Our findings are in the spirit of Osborne et al. (2000), who show that players representing central positions will not participate in meetings when there is an identical fixed cost of participation and the outcome is a compromise between the participants. We similarly find the non-participation of centrists in environments that are different from those in Osborne et al. (2000) in two fundamental ways. First, in our model, players' expenditures are variable and influence the outcome of the conflict. Second, the outcome of the conflict is the position of the player with the highest expenditure.

In the next section we provide a model of the all-pay auction with identity-dependent externalities and define players' proximity based on their preferences. We then analyze equilibrium behavior in different three-player environments. In Section 3 we conclude with a brief discussion of welfare, contests between groups, and more general assumptions on the cost of bidding.

## 2 The Model

We examine all-pay auctions with identity-dependent externalities under complete information. In an all-pay auction all players place their bids simultaneously, the player with the highest bid wins the prize, and all players pay their bid. In order to capture the idea that a player is not indifferent to who wins the prize if he does not, we represent a player's valuation of the outcome as an  $n$ -dimensional vector rather than a scalar. Each player's valuation of the outcome is a vector  $v_i = (v_{i1}, v_{i2}, \dots, v_{in})$ ,  $i \in I = \{1, \dots, n\}$ , where  $v_{ij}$  is the value to player  $i$  if player  $j$  wins the prize. Externalities are not restricted to being positive or negative only, but we assume that players strictly prefer to win the prize.

**Assumption 1**  $\forall i \in I: v_{ii} > v_{ij} \forall j \in I, j \neq i$ .

Given a profile of bids,  $b = (b_1, \dots, b_n)$ , player  $i$ 's payoff is

$$u_i(b) = \sum_{j \in I} p_j(b) v_{ij} - C(b_i),$$

where  $p_j: \mathbb{R}_+^n \rightarrow [0, 1]$  is player  $j$ 's probability of winning given the profile of bids, and  $C: \mathbb{R}_+ \rightarrow \mathbb{R}_+$  is the player's cost, which only depends on his own bid. With an auction CSF

$$p_j(b) = \begin{cases} 0 & \text{if } \exists k \in I: b_k > b_j \\ 1 & \text{if } b_j > b_k \forall k \neq j \\ \frac{1}{m} & \text{if } j \text{ ties with } m-1 \text{ other players for the high bid} \end{cases}.$$

For simplicity we assume in the following analysis that  $C(b_i) = b_i$ , i.e. players have constant unit marginal cost. However, our results hold generally if players have identical, continuous, strictly increasing, and unbounded cost functions with  $C(0) = 0$ .<sup>5</sup> We expand a player's expected utility,  $u_i(\cdot)$ , and probability of winning,  $p_i(\cdot)$ , to the domain of mixed strategies. A mixed strategy  $F_i : \mathbb{R}_+ \rightarrow [0, 1]$  of player  $i \in I$  is a cumulative probability distribution function over his bids. If a player bids zero with probability one, we refer to this strategy as *staying out* of the conflict. When a player submits a positive bid with strictly positive probability we say that he *actively participates* in the conflict.

We aim to analyze the effects that the distribution of preferences has on strategic behavior in all-pay auctions and for this purpose focus on three-player environments ( $I = \{1, 2, 3\}$ ). For these environments we define radicalism and centrism based on the profile of players' valuations. More precisely, let  $r_{ij} := v_{ii} - v_{ij}$ ,  $i, j \in I$ , be player  $i$ 's *reach*<sup>6</sup> with respect to player  $j$ , meaning that  $r_{ij}$  is the maximum player  $i$  would be willing to bid in order to outbid player  $j$ , if players  $i$  and  $j$  were the only actively competing players. To ensure an unambiguous measure of preference proximity we assume the following.

**Assumption 2** *Inter-agent antagonism is symmetric, i.e.  $r_{ij} = r_{ji} \forall i, j \in I$ .*

Under assumptions 1 and 2,  $d(i, j) := r_{ij}$  can be interpreted as a distance between players that reflects preferences over outcomes in the sense that player  $i$  (weakly) prefers the outcome where  $j$  wins over the outcome where  $k$  wins if and only if  $d(i, j) \leq d(i, k)$ ,  $i, j, k \in I$ . In fact,  $d(i, j) := r_{ij}$  has the properties of a semi-metric:

1. Non-Negativity:  $d(i, j) := r_{ij} = v_{ii} - v_{ij} \geq 0$  by assumption 1,
2. Identity of Indiscernibles:  $d(i, j) := r_{ij} = 0$  if and only if  $i = j$  also by assumption 1,
3. Symmetry:  $d(i, j) := r_{ij} = r_{ji} = d(j, i)$  by assumption 2.

Note, however, that we do not restrict our analysis to environments in which the triangle inequality holds, as there is no intuitive motivation for this property in the context. Therefore,  $d(i, j) := r_{ij}$  need not be a metric.

For example,  $d(i, j) = r_{ij}$  could be generated by a spatial preference model in which players engage in an all-pay auction to implement their distinct ideal points in a finite dimensional real issue space. Suppose players possess identical, additively separable utility functions in which the player's bid is subtracted from a subutility function decreasing in the Euclidean distance between the player's ideal point and the implemented ideal point. Whether or not the triangle inequality may be violated rests on the curvature of the identical subutility functions. If these functions are strictly concave in the Euclidean distance (reflecting increasing marginal disutility in Euclidean distance), then the triangle inequality may be violated. If the subutility functions are linear or convex in the Euclidean distance between ideal points, then the triangle inequality holds.

<sup>5</sup> In this case we can employ our analysis to a transformed bid,  $\beta = C(b)$ . We elaborate on other potential assumptions on cost in section 3.

<sup>6</sup> This definition is based on Siegel(2009) but accounts for the identity-dependent externalities.

Given this framework, we define the players' distribution of preferences based on their willingness to outbid others as well as other players' reciprocal antagonism towards them. Intuitively, a player who favors a radical outcome will generally face stronger opposition from his rivals, and in turn be willing to expend high effort to support it.

**Definition 1** A player  $i \in I$  is called *radical*,<sup>7</sup> if

$$i \in \bigcap_{r_{st} = \max\{r_{ij} | i, j \in I\}} \{s, t\}$$

**Definition 2** A player  $i \in I$  is called *centrist*, if  $i$  is not radical.

According to Definition 1 we call a player  $i$  radical if he is willing to bid up to the maximum of all reaches when competing with some other player, and additionally other players would not be willing to bid that high unless possibly if they were competing with  $i$ .

Following Esteban and Ray(1999), we refer to *extremism* as a situation where all radical players expend in expectation more effort per capita than do centrists in order to reach their preferred outcome. Alternatively, a situation in which centrists expend more effort would be referred to as *moderation*. In the following paragraphs we separately consider the cases of (A) two radical players and one centrist, (B) one radical player and two centrists, and (C) the all-pay auction without radical players.

## 2.1 Two Radicals

Let players 1 and 3 be radical and player 2 be the centrist. We consider the symmetric case where  $d(2, 1) = d(2, 3)$ . Figure 1 illustrates the ranking of the  $r_{ij}$ 's in this case. We refer to this all-pay auction as  $\Gamma_{21}$ , where 2 refers to the number of radicals and 1 to the lone centrist.

**Fig. 1:** The case of two radical players and one centrist.

We find that in any Nash equilibrium of  $\Gamma_{21}$  both radicals will actively participate. Moreover, the Nash equilibrium of  $\Gamma_{21}$  is unique and symmetric. It has the property that the centrist player stays out of the conflict. This stands in contrast to a first-price winner-pay auction in this environment. Funk(1996) shows that there exists a pure-strategy equilibrium in the environment described above, in which player 2 wins the prize with a bid of  $r_{2j}, j \in \{1, 3\}$ .

<sup>7</sup> To our knowledge no formal definition of a *radical* in a general n-player environment exists in the literature. Intuitively, Definition 1 captures the notion that if a radical player is removed from the contest, the maximal reach across all remaining pairs of players should strictly decrease. That is, the maximal willingness to pay to win decreases.

**Proposition 1 (Extremism drives out moderation)** *There exists an unique equilibrium of  $\Gamma_{21}$ . In the equilibrium of  $\Gamma_{21}$  the centrist stays out and the radical players randomize continuously up to their common reach,  $r_{13} = r_{31}$ . The two radical players apply identical strategies in equilibrium.*

The proof of Proposition 1, which is provided in A, is more complicated than the corresponding proofs for all-pay auctions without identity-dependent externalities. In the all-pay auction without identity-dependent externalities a given player  $i$ 's expected utility from placing a bid  $b_i$  depends on the probability that  $b_i$  is the highest bid. In the case of an all-pay auction with  $k$  identical prizes this is replaced by the probability that  $b_i$  is among the  $k$  highest bids; in the case of  $k$  non-identical prizes this is replaced by the respective probability of being each of the  $j$ -th highest order statistics ( $j = 1, 2, \dots, k$ ). With identity-dependent externalities the expected utility from placing a bid  $b_i$  depends not only on the probability that  $b_i$  is the highest bid, but also on the probability that each of the other players wins conditional on player  $i$  bidding  $b_i$ . Hence, in contrast to even multiple-prize all-pay auctions, it is not enough to know the probability that player  $i$ 's bid attains a certain rank-order among bids; one needs to know the probability of each of the other players placing the highest bid conditional on player  $i$  placing the bid  $b_i$ .

One implication of Proposition 1 is that an equilibrium in which only two radicals actively participate and all centrists stay out of the conflict exists even if the population share of the radical players is much smaller than that of the centrist players. This observation is formally stated in Proposition 2.

**Proposition 2 (Extremism drives out moderation with many centrists)** *Suppose  $\Gamma_{21}$  is altered by adding more players who are centrists, while maintaining the identical radical positions of players 1 and 3. Then the equilibrium described in Proposition 1 part (i) persists: all centrists stay out and the radical players 1 and 3 actively participate by randomizing continuously up to the common reach  $r_{13} = r_{31}$ .*

*Proof* Let player  $m$  be an additional player, who is centrist in comparison with players 1 and 3. Then  $r_{mj} \leq r_{jk}$  for all  $j, k \in \{1, 3\}$ ,  $j \neq k$ , and there exists a  $j \in \{1, 3\}$  such that the inequality is strict. Note that in order for players 1 and 3 to remain radical,  $r_{ml} < r_{13} \forall m, l \in I \setminus \{1, 3\}$ . If player  $m$  bids zero and all other players follow the equilibrium strategies described in Proposition 2, then  $m$ 's expected payoff is  $\frac{1}{2}(v_{m1} + v_{m3})$ . If player  $m$  places a strictly positive bid,  $b \leq r_{jk}$ , while all other players follow the

strategies described in Proposition 2,  $m$ 's expected payoff would be

$$\begin{aligned}
u_m(b) &= F(b)^2 v_{mm} + (1 - F(b))^2 \left[ \frac{v_{m1} + v_{m3}}{2} \right] - b \\
&= \frac{v_{m1} + v_{m3}}{2} + F(b)^2 \left[ \frac{r_{m1} + r_{m3}}{2} \right] - b \\
&= \frac{v_{m1} + v_{m3}}{2} + \left( \frac{b}{r_{jk}} \right)^2 \left[ \frac{r_{m1} + r_{m3}}{2} \right] - b \\
&= \frac{v_{m1} + v_{m3}}{2} + b \underbrace{\left[ \underbrace{\frac{b}{r_{jk}}}_{\leq 1} \left( \underbrace{\frac{\frac{1}{2}(r_{m1} + r_{m3})}{r_{jk}}}_{< 1} \right) - 1 \right]}_{< 0} \\
&< \frac{v_{m1} + v_{m3}}{2}.
\end{aligned}$$

If player  $m$  bids more than  $r_{jk}$ , then his payoff is

$$u_m(b) = v_{mm} - b < v_{mm} - r_{jk} < v_{mm} - \frac{1}{2}(r_{m1} + r_{m3}) = \frac{v_{m1} + v_{m3}}{2}.$$

Consequently, player  $m$  optimally bids zero and all centrists stay out.

Before proceeding to the next case, we provide an example which illustrates the results above and allows us to compare the all-pay auction with a different form of all-pay contest, namely a Tullock-type model with a lottery contest success function. For the purpose of comparison we consider an example given by Linster(1993) which applies to this setting.

*Example 1* Consider three players and normalize the value of the prize to one. Players' valuations are  $v_1 = (1, \gamma, \gamma^2)$ ,  $v_2 = (\gamma, 1, \gamma)$ ,  $v_3 = (\gamma^2, \gamma, 1)$  where  $\gamma \in [0, 1)$ . The order of players' reaches is illustrated in the following diagram (Figure 2), which shows that player 2 is a centrist player and players 1 and 3 are radical. By Proposition

**Fig. 2:** Illustration of players' preferences in Example 1.

1 in the unique equilibrium player 2 stays out of the conflict, i.e.  $F_2(x) = 1$  for all  $x \geq 0$ , and players 1 and 3 randomize symmetrically over  $[0, r_{13}]$  using the cdf

$$F_1(x) = F_3(x) = \begin{cases} 0 & x < 0 \\ \frac{x}{1 - \gamma^2} & 0 \leq x \leq 1 - \gamma^2 \\ 1 & x > 1 - \gamma^2 \end{cases}.$$

In this environment the outcome that the centrist, player 2, wins is socially optimal in the sense that it maximizes the sum of all players' valuations<sup>8</sup>. In the unique equilibrium of the all-pay auction described above, this socially optimal outcome will be achieved with probability zero as compared to a probability equal to  $(1 - \gamma)/(3 - \gamma)$  in the Tullock game with lottery contest success function as considered by Linster(1993). Moreover, the expected sum of bids is strictly greater in the all-pay auction  $\left(1 - \gamma^2 > \frac{2}{3-\gamma} \cdot (1 - \gamma)\right)$ , although the centrist submits a strictly positive bid  $\left(2 \frac{(1-\gamma)^2}{(3-\gamma)^2} > 0\right)$  in the lottery contest.

## 2.2 One Radical

Now consider a three player setup with only one radical player. Assume player 2 is the radical player and that the two centrist players, 1 and 3, are symmetric. We refer to this game as  $\Gamma_{12}$ . Figure 3 illustrates players' preferences over outcomes. We find that

**Fig. 3:** The case of one radical player and two centrists.

there exists an equilibrium in  $\Gamma_{12}$  in which one of the centrist players stays out of the contest, while the radical player always actively participates in equilibrium. Moreover, even in a symmetric equilibrium (in which all players participate) extremism persists.<sup>9</sup>

**Proposition 3 (Moderation does not drive out extremism)** *In  $\Gamma_{12}$ , the radical always actively participates in the conflict.*

*Proof* Assume that player 2 stays out of the contest. Then his expected payoff would be  $v_{2j}$ ,  $j \in \{1, 3\}$ , and players 1 and 3 would randomize uniformly over  $[0, r_{jk}]$ ,  $j, k \in \{1, 3\}$ ,  $j \neq k$ . Thus, if player 2 would bid  $x = r_{jk}$ , he would win with certainty and receive expected payoff  $v_{22} - r_{jk} > v_{22} - r_{2j} = v_{2j}$ .

<sup>8</sup> Generally the concept of social welfare additionally takes expenditure into account. We follow Jehiel and Moldovanu (2006) and Linster (1993) by using the sum of valuations to measure social welfare in a context of contests with identity-dependent externalities. This interpretation implies that the players' expenditures are considered transfers. In some conflicts which are covered by our model, e.g. political lobbying, expenditures are often more accurately viewed as a social waste of resources. Therefore, we additionally discuss the effects of the auction CSF on expected total expenditure. We further elaborate on this issue in the conclusion.

<sup>9</sup> Even if the valuation vectors were slightly perturbed in a way such that players 1 and 3 were no longer symmetric the main conclusions of Propositions 3 and 4 continue to hold in the sense that the player who was previously the radical will always continue to actively participate in the conflict and for each player who was previously a centrist there exists an equilibrium in which he stays out of the conflict. This is true even though one of the players previously a centrist is a radical in the perturbed game (see Klose and Kovenock, 2013).

**Proposition 4 (Extremism drives out moderation)** *In  $\Gamma_{12}$ , for each centrist player  $i \in \{1, 3\}$  there exists an equilibrium in which player  $i$  stays out of the conflict, i.e.  $F_i(x) = 1$  for all  $x \geq 0$ .*

*Proof* Without loss of generality assume that  $F_1(x) = 1$  for all  $x \geq 0$ . From the standard arguments for all-pay auctions (Baye et al., 1996) players 2 and 3 randomize uniformly over  $[0, r_{23}]$ . Both players must earn their equilibrium payoff at the upper bound of the support of their equilibrium strategies. Thus, player 3's expected payoff from a bid  $x \in [0, r_{23}]$  must be  $v_{32}$  and player 2's expected payoff from a bid  $x \in [0, r_{23}]$  must be  $v_{23}$ . Consequently, players 2's and 3's equilibrium strategies are

$$F_2(x) = F_3(x) = \begin{cases} 0 & x < 0 \\ \frac{x}{r_{23}} & 0 \leq x \leq r_{23} \\ 1 & x > r_{23} \end{cases} .$$

Given these strategies it is optimal for player 1 to bid zero and receive expected payoff  $\frac{1}{2}(v_{12} + v_{13})$ , because any bid  $x \in (0, r_{13})$  would yield an expected payoff of

$$\begin{aligned} u_1(x, F_{-1}) &= -x + v_{11}F_2(x)F_3(x) + v_{13}F_2(x)(1 - F_3(x)) + v_{12}F_3(x)(1 - F_2(x)) \\ &\quad + v_{13} \int_x^{r_{13}} (1 - F_3(s))f_2(s)ds + v_{12} \int_x^{r_{13}} (1 - F_2(s))f_3(s)ds \\ &= \frac{v_{12} + v_{13}}{2} - x \left[ 1 - \frac{x}{r_{31}^2} \left( v_{11} - \frac{v_{12} + v_{13}}{2} \right) \right] < \frac{v_{12} + v_{13}}{2} . \end{aligned}$$

In the environment with one radical player, it is not necessary that a centrist player completely stays out of the contest. However, even in the symmetric equilibrium in which both centrists actively participate, extremism is present.

**Proposition 5 (Extremism)** *In  $\Gamma_{12}$ , there exists a symmetric equilibrium (in the sense that identical players use identical strategies). This equilibrium exhibits extremism, and the radical player expends more effort than any centrist player in the sense of first order stochastic dominance.*

Proof of Proposition 5 is provided in B.

Linster's (1993) second example takes on exactly this configuration of preferences assuming the lottery CSF. In Example 2 we compare his results to those obtained when applying the auction CSF.

*Example 2* Consider three players and normalize the value of the prize to one. Players' valuations are  $v_1 = (1, 0, \gamma)$ ,  $v_2 = (0, 1, 0)$ , and  $v_3 = (\gamma, 0, 1)$ , where  $\gamma \in [0, 1)$ . The order of players' reaches is illustrated in Figure 4, showing that player 2 is a radical player and players 1 and 3 are centrists. For the lottery CSF, Linster(1993) computes for this example that the centrists bid  $\frac{2}{(3+\gamma)^2}$  each and the radical bids  $(1 + \gamma)\frac{2}{(3+\gamma)^2}$ . The expected sum of bids is  $2/(3 + \gamma) \in (\frac{1}{2}, \frac{2}{3}]$ , and player 2 wins with probability  $\frac{1+\gamma}{3+\gamma} \in [\frac{1}{3}, \frac{1}{2})$ , which is increasing in  $\gamma$ .

On the other hand, in the asymmetric equilibrium of the all-pay auction (described in Proposition 4) players expend on average higher effort (the expected sum of bids is 1) and the least socially desirable outcome, i.e. player 2 wins, is more likely to

**Fig. 4:** Illustration of players' preferences in Example 2.

occur (2 wins with probability  $\frac{1}{2}$ ). The symmetric equilibrium yields higher payoffs to the players who participate in the asymmetric equilibrium in which one centrist stays out. In this example all players have equal expected payoff,  $(\frac{\gamma}{2})^{\frac{2}{2-\gamma}}$ , in the symmetric equilibrium, while both active players in the asymmetric equilibrium have an expected payoff of zero. The centrist who stays out receives in expectation  $\frac{\gamma}{2} > (\frac{\gamma}{2})^{\frac{2}{2-\gamma}}$  in the asymmetric equilibrium. However, the sum of expected payoffs is strictly greater in the symmetric equilibrium.

### 2.3 No Radicals

Under the assumption of symmetric antagonism, there is only one three-player environment without any radical players. All reaches must coincide,  $r_{ij} = r_{kl}, \forall i, j, k, l \in I, i \neq j, k \neq l$ . This case is illustrated in Figure 5.

**Fig. 5:** The case of symmetric antagonism and no radical players.

This case is equivalent to a three player all-pay auction without identity-dependent externalities in which players are symmetric and value the prize at  $r_{ij}, i, j \in I, i \neq j$ . Baye, Kovenock and De Vries (1996) show that there exists a unique symmetric equilibrium as well as a continuum of asymmetric equilibria. All equilibria however yield the same expected payoffs ( $v_{ij}, i \neq j$  after rescaling) for each player and the same expected total expenditures.

### 3 Conclusion

In this paper, we demonstrated that the distribution of player preferences substantially influences players' behavior in all-pay auctions with identity-dependent externalities. Specifically, we showed that in these contests extremism, characterized by a higher per capita expenditure by radicals than centrists, may prevail to such an extent that

radicals may expend more in the aggregate than centrists, even if they are relatively small in number. In fact, centrists may in the aggregate expend zero, even if they vastly outnumber radicals.

One consequence of this behavior is that, radical outcomes may occur with greater frequency than centrist outcomes, even in environments with a small ratio of radicals to centrists. In fact, as demonstrated in Proposition 2, centrists may vastly outnumber radicals and expend zero in the aggregate, yielding a radical outcome with certainty.

In these conflicts there is no uniform benchmark for the analysis of welfare. The discussion of welfare in the literature to date has focused on the likelihood that the final outcome maximizes the sum of the players' valuations (see for instance Linster, 1993, and Jehiel and Moldovanu, 2001). This measure appears to extend in a natural way the definition of efficiency from the auction literature (e.g. Maskin, 2000) to contests with identity-dependent externalities. Since a moderate outcome in our examples maximizes the sum of the valuations among all potential outcomes (i.e., individual player positions), social optimality is unlikely to result. Konrad (2006) points out that the sum of the players' valuations is an appropriate measure of social welfare in cases in which effort is simply a transfer. Of course, the literature on rent seeking following Tullock (1967) has viewed at least part of the expenditure in a conflict to be social waste (see for instance Tullock, 1980, and Fudenberg and Tirole, 1987). In this case the existence of radicals, by tending to increase expenditure, also increases whatever waste might arise from those expenditures.

We presented two examples that illustrated similarities (e.g., existence of extremism) as well as differences (e.g., participation vs. non-participation of centrists) that resulted from employing an auction contest success function rather than the lottery contest success function, which is prominent in the literature. Our results illustrate the importance of the choice of the institutions of conflict, as modeled by the contest success function, in determining the role of extremism and moderation in economic, political and social environments.

There are several extensions of our model that follow immediately from our analysis and address specific assumptions. One assumption made throughout the paper is that individuals do not form coalitions to promote a group's position but rather expend resources to promote an individually preferred outcome. However this is, in fact, also consistent with standard models of non-cooperative behavior in coalitions. Indeed, under the common assumption that individuals within a coalition choose their strategies non-cooperatively, our analysis does in fact apply to all-pay auctions between exogenously determined groups<sup>10</sup> for a group-specific public-good prize<sup>11</sup>. Baik et al. (2001) show that if two groups compete in an all-pay auction for a public-good prize, then there exists a Nash equilibrium in which only the player who has the highest valuation of the prize within his group actively participates in the conflict,

<sup>10</sup> The assumption that groups are exogenously determined is common in the literature on contests between groups. The strategic formation of groups in contests is addressed in e.g. Baik and Lee (2001), Skaperdas (1998).

<sup>11</sup> In this type of contest a group's probability of winning depends on their total effort and all members of the winning group receive their valuation of winning (e.g. Baik (1993), Baik et al. (2001), Esteban and Ray (1999)). Alternatively groups may compete for a private-good prize, whereupon the prize allocated within the winning group through a second stage contest (e.g. Katz and Tokatlidu (1996), Konrad and Kovenock (2009)) or a previously determined sharing rule (Baik and Lee, 2001)

and all remaining group members free ride. This result can be generalized to three and more groups and to all-pay auctions with identity-dependent externalities. In particular, in a non-cooperative conflict between three groups of individuals who have heterogeneous valuations of the outcome promoted by their group and the other two alternatives, there exists a Nash equilibrium in which (at most) the individual with the highest willingness to bid within each group will actively participate in equilibrium. Therefore, our results for the three player model also apply to conflict between three groups when players make their decisions non-cooperatively and, thus, may free ride on other group members' efforts. By assumption, Esteban and Ray (1999) disallow free riding. In their model group members' preferences are homogenous and all players within the same group choose identical effort levels. This together with their assumption of identical convex cost technologies result in cost advantages of larger groups, which may be significant enough to result in moderation.

Another assumption that we maintain throughout our analysis is that players face identical cost functions. With heterogeneous costs the notion of player  $i$ 's reach with respect to player  $j$  needs to be adjusted in order to accurately reflect the player's willingness to bid. Let player  $i$ 's cost of bidding be given by a continuous, strictly increasing, unbounded function  $c_i : \mathbb{R}_+ \rightarrow \mathbb{R}_+$ , with  $c_i(0) = 0$ . Then player  $i$ 's reach with respect to player  $j$  is  $r_{ij} = c_i^{-1}(v_{ii} - v_{ij})$ .

With heterogeneous costs the reaches  $r_{ij}$  generally do not satisfy Assumption 2, so we omit a formal analysis.<sup>12</sup> Moreover, it is clear that such an analysis is somewhat more complicated in the presence of identity-dependent externalities than in the original analysis of Siegel (2009, 2010). First, we do not have the generic uniqueness of equilibrium payoffs (Siegel(2009)) to aid in tying down distributions. Second, because the payoff of a player at any bid  $b$  depends not only on the probability that he is outbid at that bid, but on the conditional probability that each of the other players is the highest bidder, there is no obvious extension of the Siegel (2010) algorithm to pin down equilibrium distributions or the set of active bidders.

Nonetheless, we can say something about certain classes of asymmetric cost functions. Suppose, for instance, that players have cost functions of the form employed by Moldovanu and Sela (2001) and in Siegel's (2010) analysis of *simple contests*,  $c_i(b) = \gamma_i C(b)$ , where  $\gamma_i > 0$  for all  $i \in I$  and  $C(b)$  is continuous, strictly increasing, and unbounded with  $C(0) = 0$ . Moreover, suppose that in the game  $\Gamma_{21}$  described in section 2.1, the two radicals (based on preferences over outcomes in the original game  $\Gamma_{21}$  with cost  $C(b) = b$ ) have a common coefficient of cost,  $\gamma_i = \gamma_R, i = 1, 3$ , which is strictly less than the corresponding coefficient of the single centrist,  $\gamma_2 = \gamma_N$ . Then the results of Proposition 4 continues to hold, with proofs modified to account for the fact that, with the cost asymmetry,  $r_{21} = r_{23} < r_{32} = r_{12}$ . Similarly, the result of Proposition 2 of the game with two radicals and multiple centrists would continue to hold if any centrist player  $i$  (based on the preferences in the original game) has a coefficient  $\gamma_i \geq \gamma_R$ . On the other hand, if an original centrist exhibits low enough costs of effort this may cause him to actively participate in the conflict, and may improve welfare.

<sup>12</sup> See, however, Klose and Kovenock (2013) for an analysis of all-pay auctions with identity-dependent externalities and more general preference structures.

In a similar fashion, Propositions 3-5 in section 2.2 continue to hold under the assumption that the two centrists in the game  $\Gamma_{12}$  have an identical coefficient of cost  $\gamma_i = \gamma_N, i = 1, 3$ , which is greater than the coefficient of the sole radical,  $\gamma_2 = \gamma_R$ . Of course, there are other formulations of cost for which similar results arise. One example is an appropriate choice of budget constraints. In fact, a general extension to budget constrained costs along the lines of Che and Gale's (1998) analysis of standard all-pay auctions raises new and interesting phenomena. For instance, if a sufficiently small budget constraint is imposed upon a radical player, the likelihood that a centrist wins the conflict may increase, thereby increasing the expected sum of valuations from the resulting outcome. These and other explorations of all-pay auctions with identity-dependent externalities are left for future research.

## A Proof of Proposition 1

*Proof* In a first step we show existence by constructing an equilibrium, we then show uniqueness of the equilibrium described before in a second step involving multiple lemmas.

The strategy profile in which 2 stays out completely (puts mass 1 on zero) and players 1 and 3 randomize uniformly over  $[0, r_{jk}]$  ( $j, k \in \{1, 3\}$ ,  $j \neq k$ ) is a Nash equilibrium. Assume that 2 uses the strategy  $F_2(x) = \begin{cases} 0 & \text{for } x < 0 \\ 1 & \text{for } x \geq 0 \end{cases}$ . Then (by Baye et al., 1996) it is optimal for players 1 and 3 to randomize over  $[0, r_{jk}]$  according to

$$F(x) = \begin{cases} 0 & \text{for } x < 0 \\ \frac{x}{r_{jk}} & \text{for } 0 \leq x \leq r_{jk} \\ 1 & \text{for } x > r_{jk} \end{cases}$$

Given that 1 and 3 apply this strategy player 2's payoff if he submits a strictly positive bid  $x \in (0, r_{2j}]$  is:

$$\begin{aligned} u_2^*(x) &= [F(x)]^2 v_{22} + (1 - [F(x)]^2) v_{2j} - x \\ &= v_{2j} + F(x)^2 r_{2j} - x \\ &= v_{2j} - x \left( 1 - \frac{x}{r_{jk}} \frac{r_{2j}}{r_{jk}} \right) \\ &< v_{2j}. \end{aligned}$$

It is therefore a best response for player 2 to stay out of the conflict.

Next we prove the uniqueness of the equilibrium described in Proposition 1, by first showing that any equilibrium of  $\Gamma_{21}$  is symmetric in the sense that both radicals (players 1 and 3) choose identical strategies. In a second step we then show that the set of symmetric equilibria of  $\Gamma_{21}$  is a singleton, given by the cut-throat competition equilibrium described above.

Let  $\underline{s}_i$  and  $\bar{s}_i$  be the lower and upper bound, respectively, of the support of an equilibrium strategy for player  $i$ ,  $i \in I$ , and define  $\bar{s} = \max_{i \in I} \{\bar{s}_i\}$ . In the following, the indices  $j$  and  $k$  refer to two different radical players, i.e.  $j \in \{1, 3\}$ ,  $k \in \{1, 3\} \setminus \{j\}$ .

**Lemma 1** *In any equilibrium of  $\Gamma_{21}$ , both radicals actively participate in the conflict.*

*Proof* By way of contradiction, assume that one of the radical players stays out of the conflict; without loss of generality let that player be player 1, i.e.  $F_1(0) = 1$ . Given player 1's strategy players 2 and 3 would randomize up to  $r_{23} = r_{32} < r_{31} = r_{13}$ . Player 1's payoff if he bids zero will be in the interval  $(v_{13}, v_{12})$  and he could strictly improve upon this by bidding  $r_{23}$  which would guarantee him a payoff of  $v_{11} - r_{23} = v_{11} - r_{12} = v_{12}$ .

**Lemma 2**  $s_i = 0$  for all  $i \in I$ , and for at least one player  $l \in I$ ,  $F_l(0) = 0$ .

*Proof* Assume  $s_i > s_l \geq s_m \geq 0$  for some  $i, l, m \in I$ . Any bid  $x \in [0, s_i]$  results in a loss with certainty. Therefore, players  $l$  and  $m$  do not put mass anywhere over  $(0, s_i]$ . Moreover, no player  $l$  or  $m$  can place a mass point at  $s_i$ , because if two or more players had a mass point at  $s_i$ , then one could improve by moving mass up, and if only one player had a mass point at  $s_i$ , then he would improve by moving the mass down. Altogether players  $l$  and  $m$  do not put mass anywhere over  $(0, s_i]$ , but then player  $i$  would improve by moving mass down. This contradiction implies that there exist mutually different  $i, l, m \in I$  such that  $s_i = s_l \geq s_m \geq 0$ . Assume that  $s_i = s_l > s_m \geq 0$  for some  $i, l, m \in I$ . It cannot be the case that both players,  $i$  and  $l$ , have a mass point at  $s_i = s_l$  (otherwise one could improve by moving mass up slightly), but then at least one of them would win with probability arbitrarily close to zero in some neighborhood above  $s_i$  and would be better off by moving mass down to zero. It follows that in equilibrium  $s_1 = s_2 = s_3 = s$ . It cannot be the case that all three players have a mass point at  $s$  otherwise a player could improve by moving this mass up slightly. Therefore, at least one player loses with certainty at  $s$ . Altogether this shows that  $s_1 = s_2 = s_3 = 0$ .

**Lemma 3** There are no mass points at  $x$  in any player's equilibrium distribution  $\forall x \in (0, \bar{s}]$ .

*Proof* Suppose player  $i \in I$  has a mass point at  $x \in (0, \bar{s}]$ . Since, from Lemma 2,  $F_l(x) > 0$  for every  $l \in I$ , for sufficiently small  $\varepsilon > 0$  no player  $j \neq i$  would place mass in  $(x - \varepsilon, x]$  since that player could improve his payoff by moving mass from that interval to infinitesimally above  $x$ . But then it is not optimal for  $i$  to put mass at  $x$ .

**Lemma 4**  $\bar{s}_1 = \bar{s}_3 > \bar{s}_2$ .

*Proof* Obviously, it cannot be the case that  $\bar{s}_i > \bar{s}_l \geq \bar{s}_m$  for some  $i, l, m \in I$ , because player  $i$  would strictly improve his payoff by moving mass from  $(\frac{1}{2}(\bar{s}_l + \bar{s}_i), \bar{s}_i]$  down to  $\frac{1}{2}(\bar{s}_l + \bar{s}_i)$ . Suppose,  $\bar{s}_1 = \bar{s}_2 = \bar{s}_3 = \bar{s} > 0$ . Since any bid  $b_2 > r_{2j}$  of player 2 is strictly dominated by  $b_2 = 0$  it follows that  $\bar{s} \leq r_{2j}$ . By Lemma 2,  $s_i = 0$  for all  $i \in I$  and at most two players may have a mass point at zero. Therefore, there exists a radical player  $j$ , who is outbid with certainty when bidding zero and whose payoff from bidding zero is  $u_j^*(0) = \alpha v_{j2} + (1 - \alpha)v_{jk}$  for some  $\alpha \in (0, 1)$ . By assumption  $r_{jk} > r_{j2}$  which implies by definition that  $v_{jk} < v_{j2}$ . Then, (by Lemma 2) player  $j$ 's expected equilibrium payoff would be  $u_j^* < v_{j2}$ . On the other hand, by submitting a bid  $\bar{s} + \varepsilon$  greater than  $\bar{s}$  player  $j$  would receive  $u_j^*(\bar{s} + \varepsilon) = v_{jj} - \bar{s} - \varepsilon \geq v_{jj} - r_{j2} - \varepsilon = v_{j2} - \varepsilon$ . Therefore, by choosing  $\varepsilon > 0$  small enough, he would improve his payoff. Thus,  $\bar{s}_1 = \bar{s}_2 = \bar{s}_3$  cannot hold true. By the same argument it cannot be the case that  $\bar{s}_j < \bar{s}_2 = \bar{s}_k = \bar{s}$ . Hence,  $\bar{s}_j = \bar{s}_k > \bar{s}_2$ .

**Lemma 5**  $\bar{s}_2 < r_{2j}, j \in \{1, 3\}$ .

*Proof* By Lemma 4 player 2 loses with strictly positive probability at  $\bar{s}_2$ . Suppose  $\bar{s}_2 \geq r_{2j}$ , then player 2's equilibrium payoff at  $\bar{s}_2$  is

$$\begin{aligned} u_2^*(\bar{s}_2, F_j, F_k) &= [F_j(\bar{s}_2) \cdot F_k(\bar{s}_2)]v_{22} + (1 - [F_j(\bar{s}_2) \cdot F_k(\bar{s}_2)])v_{2j} - \bar{s}_2 \\ &\leq v_{2j} - \underbrace{(1 - [F_j(\bar{s}_2) \cdot F_k(\bar{s}_2)])}_{>0 \text{ by Lemma 4}} r_{2j} < v_{2j}. \end{aligned}$$

This is a contradiction, because player 2 could guarantee himself a payoff of at least  $v_{2j}$  by bidding zero.

**Lemma 6** Players  $j \in \{1, 3\}$  earn expected equilibrium payoffs  $v_{jj} - \bar{s}$ .

*Proof* From Lemmas 3 and 4 players 1 and 3 must earn their expected equilibrium payoff at the upper bound of the support of their mixed strategies,  $\bar{s}$ , and neither has a mass point at  $\bar{s}$ . Therefore, their expected equilibrium payoff is  $u_j^* = v_{jj} - \bar{s}$ .

**Lemma 7**  $F_1(x) = F_3(x)$  for all  $x \in [\bar{s}_2, \bar{s}]$ .

*Proof* Notice that  $F_2(x) = 1$  for all  $x \in [\bar{s}_2, \bar{s}]$ , and  $F_1(\bar{s}) = F_3(\bar{s}) = 1$ . From Lemma 4, for  $x \in (\bar{s}_2, \bar{s})$

$$u_j(x, F_2, F_k) = F_k(x)v_{jj} + (1 - F_k(x))v_{jk} - x = v_{jk} + F_k(x)r_{jk} - x.$$

By Lemma 6 it follows that

$$\begin{aligned} v_{jk} + F_k(x)r_{jk} - x &= v_{jj} - \bar{s} \\ \Leftrightarrow F_k(x) &= 1 - \frac{\bar{s} - x}{r_{jk}} \end{aligned}$$

and by Assumption 2 (symmetric inter-agent antagonism) follows that players  $j$  and  $k$  use identical strategies  $F_j(x) = F_k(x) = 1 - \frac{\bar{s} - x}{r_{jk}}$  over the interval  $(\bar{s}_2, \bar{s})$ . If  $\bar{s}_2 > 0$ , then by Lemma 3 this holds over  $[\bar{s}_2, \bar{s}]$ . If  $\bar{s}_2 = 0$  right-continuity of  $F_i, i \in I$ , implies  $F_1(0) = F_3(0)$ .

**Lemma 8** For any nondegenerate interval  $[\underline{t}, \bar{t}] \in [0, \bar{s}]$  ( $\underline{t} < \bar{t}$ ) there are at least two players,  $i, j \in I$ , such that  $F_i(\bar{t}) - F_i(\underline{t}) > 0$  for  $l = i, j$ .

*Proof* Suppose there is a  $t > \underline{t}$  such that  $F_i(t) - F_i(\underline{t}) = 0$  for all  $i \in I$ , and let  $\bar{t}$  be the supremum over all  $t$  with this property, i.e. define  $\bar{t} = \sup\{t > \underline{t} : F_i(t) - F_i(\underline{t}) = 0 \text{ for all } i \in I\}$ . Notice that by Lemma 2  $\underline{t} > 0$ . Since  $\bar{t} > \underline{t} \geq 0$  no player has a mass point at  $\bar{t}$  by Lemma 3. Let player  $i \in I$  and  $m, l \in I \setminus \{i\}$ , then player  $i$ 's payoff from a bid  $\bar{t} + \varepsilon$  is

$$\begin{aligned} u_i(\bar{t} + \varepsilon, F_l, F_m) &= v_{ii} \cdot F_l(\bar{t} + \varepsilon)F_m(\bar{t} + \varepsilon) + v_{il} \int_{\bar{t} + \varepsilon}^{\bar{s}} F_m(y)f_l(y)dy \\ &\quad + v_{im} \int_{\bar{t} + \varepsilon}^{\bar{s}} F_l(y)f_m(y)dy - \bar{t} - \varepsilon. \end{aligned}$$

On the other hand player  $i$ 's payoff from bidding  $\underline{t}$  is

$$\begin{aligned} u_i(\underline{t}, F_l, F_m) &= v_{ii} \cdot F_l(\underline{t})F_m(\underline{t}) + v_{il} \int_{\underline{t}}^{\bar{s}} F_m(y)f_l(y)dy + v_{im} \int_{\underline{t}}^{\bar{s}} F_l(y)f_m(y)dy - \underline{t} \\ &= v_{ii} \cdot F_l(\bar{t})F_m(\bar{t}) + v_{il} \int_{\bar{t}}^{\bar{s}} F_m(y)f_l(y)dy + v_{im} \int_{\bar{t}}^{\bar{s}} F_l(y)f_m(y)dy - \underline{t}, \end{aligned}$$

which is strictly greater than  $u_i(\bar{t} + \varepsilon, F_l, F_m)$  for  $\varepsilon > 0$  sufficiently small. Thus, for small enough  $\varepsilon > 0$  a player would improve his payoff by moving mass from  $[\bar{t}, \bar{t} + \varepsilon]$  to  $\underline{t}$ . Therefore, no  $t > \underline{t}$  such that  $F_i(t) - F_i(\underline{t}) = 0$  for all  $i \in I$  exists.

Suppose that there is only one player  $i \in I$  with  $F_i(\bar{t}) - F_i(\underline{t}) > 0$ , and denote the other two players by  $l, m \in I \setminus \{i\}$ . Note that for players  $p \in \{l, m\}$ ,  $f_p(t) = 0$  for all  $t \in (\underline{t}, \bar{t})$  and  $F_p(\underline{t}) = F_p(t) = F_p(\bar{t})$  for all  $t \in (\underline{t}, \bar{t})$ . Player  $i$ 's expected payoff from a bid  $t \in (\underline{t}, \bar{t})$  is

$$\begin{aligned} u_i(t, F_l, F_m) &= v_{ii} \cdot F_l(t)F_m(t) + v_{il} \int_t^{\bar{s}} F_m(y)f_l(y)dy + v_{im} \int_t^{\bar{s}} F_l(y)f_m(y)dy - t \\ &= v_{ii} \cdot F_l(\underline{t})F_m(\underline{t}) + v_{il} \int_{\underline{t}}^{\bar{s}} F_m(y)f_l(y)dy + v_{im} \int_{\underline{t}}^{\bar{s}} F_l(y)f_m(y)dy - t \\ &< v_{ii} \cdot F_l(\underline{t})F_m(\underline{t}) + v_{il} \int_{\underline{t}}^{\bar{s}} F_m(y)f_l(y)dy + v_{im} \int_{\underline{t}}^{\bar{s}} F_l(y)f_m(y)dy - \underline{t} \\ &= u_i(\underline{t}, F_l, F_m). \end{aligned}$$

Therefore, player  $i$  could improve his payoff by moving mass from the interval  $(\underline{t}, \bar{t}]$  to its lower bound  $\underline{t}$ .

**Lemma 9**  $F_1(x) = F_3(x)$  for all  $x \in [0, \bar{s}]$ .

*Proof* If  $\bar{s}_2 = 0$  then  $F_1(x) = F_3(x)$  for all  $x \in [0, \bar{s}]$  by 7, thus we assume in the following that  $\bar{s}_2 > 0$ . For any bid  $b_j > 0$  in the support of player  $j$ 's equilibrium strategy his expected payoff must be equal to  $v_{jj} - \bar{s}$  (by Lemma 6). That is:<sup>13</sup>

$$\begin{aligned}
v_{jj} - \bar{s} &= v_{jj} \cdot (1 - p\{2 \text{ wins} | b_j\} - p\{k \text{ wins} | b_j\}) + v_{j2} \cdot p\{2 \text{ wins} | b_j\} \\
&\quad + v_{jk} \cdot p\{k \text{ wins} | b_j\} - b_j \\
&= v_{jj} - r_{j2} \cdot p\{2 \text{ wins} | b_j\} - r_{jk} \cdot p\{k \text{ wins} | b_j\} - b_j \\
&= v_{jj} - r_{j2} \cdot \int_{b_j}^{\bar{s}} F_k(y) f_2(y) dy - r_{jk} \cdot \int_{b_j}^{\bar{s}} F_2(y) f_k(y) dy - b_j \\
&= v_{jj} - r_{j2} \cdot \int_{b_j}^{\bar{s}} F_k(y) f_2(y) dy \\
&\quad - r_{jk} \cdot \left( [F_2(y) F_k(y)]_{b_j}^{\bar{s}} - \int_{b_j}^{\bar{s}} F_k(y) f_2(y) dy \right) - b_j \\
&= v_{jj} - (r_{j2} - r_{jk}) \cdot \int_{b_j}^{\bar{s}} F_k(y) f_2(y) dy - r_{jk} \cdot (1 - F_2(b_j) F_k(b_j)) - b_j \\
&\Leftrightarrow \bar{s} - b_j = (r_{j2} - r_{jk}) \cdot \int_{b_j}^{\bar{s}} F_k(y) f_2(y) dy + r_{jk} \cdot (1 - F_2(b_j) F_k(b_j))
\end{aligned}$$

Define  $\alpha, \beta, \gamma$  such that  $\alpha \equiv r_{12} = r_{21} = r_{32} = r_{23}$ ,  $\beta \equiv r_{13} = r_{31}$ , and  $\gamma = \alpha - \beta$ . Note that  $\alpha, \beta > 0$  and  $\gamma < 0$ . Then for any  $b_j, b_k \in (0, \bar{s}]$ :

$$\bar{s} - b_j \leq \gamma \cdot \int_{b_j}^{\bar{s}} F_k(s) f_2(s) ds + \beta \cdot (1 - F_2(b_j) F_k(b_j)), \quad (\text{A.1.1})$$

and

$$\bar{s} - b_k \leq \gamma \cdot \int_{b_k}^{\bar{s}} F_j(s) f_2(s) ds + \beta \cdot (1 - F_2(b_k) F_j(b_k)), \quad (\text{A.1.2})$$

where equality must hold in A.1.1 for bids  $b_j$  in the support of player  $j$ 's equilibrium strategy and in A.1.2 for  $b_k$  in the support of player  $k$ 's equilibrium strategy.

By way of contradiction, assume that there exists some  $b_0 > 0$  such that  $F_1(b_0) \neq F_3(b_0)$ . By Lemma 3  $F_1$  and  $F_3$  are continuous everywhere on  $(0, \bar{s}]$  and by Lemma 7  $F_1(\bar{s}_2) = F_3(\bar{s}_2)$ . This implies that either there exists an interval  $[x, y] \subset (0, \bar{s}_2]$  such that  $F_1(x) = F_3(x)$ ,  $F_1(y) = F_3(y)$ , and  $F_1(b) \neq F_3(b) \forall b \in (x, y)$ , or there exists  $\bar{x} > b_0$  such that  $F_1(b) = F_3(b) \forall b \geq \bar{x}$  and  $F_1(b) \neq F_3(b) \forall b \in [0, \bar{x})$ .

Suppose that  $[x, y]$  is an interval such that  $F_1(x) = F_3(x)$ ,  $F_1(y) = F_3(y)$ , and  $F_1(b) \neq F_3(b) \forall b \in (x, y)$ . We treat the following four cases separately:

1.  $x, y \in \text{supp}_j \cap \text{supp}_k$ , where  $\text{supp}_i$  denotes the support of player  $i$ 's equilibrium strategy. Without loss of generality let  $F_j(b) > F_k(b)$  for all  $b \in (x, y)$ . In this case by (A.1.1) and (A.1.2) at  $b = y$

$$\gamma \cdot \int_y^{\bar{s}} F_k(s) f_2(s) ds + \beta \cdot (1 - F_2(y) F_k(y)) = \gamma \cdot \int_y^{\bar{s}} F_j(s) f_2(s) ds + \beta \cdot (1 - F_2(y) F_j(y))$$

if and only if

$$\gamma \cdot \int_y^{\bar{s}} (F_j(s) - F_k(s)) f_2(s) ds = \beta F_2(y) \cdot \underbrace{(F_j(y) - F_k(y))}_{=0} = 0$$

By definition  $\gamma < 0$ , hence

$$\int_y^{\bar{s}} (F_j(s) - F_k(s)) f_2(s) ds = 0.$$

Similarly, at  $b = x$

$$\int_x^{\bar{s}} (F_j(s) - F_k(s)) f_2(s) ds = 0.$$

<sup>13</sup> We let  $p\{i \text{ wins} | b_j\}$  denote the probability that player  $i$  wins conditional on the event that player  $j$  bids  $b_j$ .

Then, by

$$\int_x^{\bar{s}} (F_j(s) - F_k(s))f_2(s)ds = \int_x^y (F_j(s) - F_k(s))f_2(s)ds + \int_y^{\bar{s}} (F_j(s) - F_k(s))f_2(s)ds$$

follows that

$$\int_x^y (F_j(s) - F_k(s))f_2(s)ds = 0.$$

If  $f_2(s) > 0$  for any  $s \in (x, y)$  this contradicts  $F_j(s) > F_k(s) \forall s \in (x, y)$ .

If  $f_2(s) = 0$  for all  $s \in (x, y)$ , then by Lemma 8  $[x, y] \in \text{supp}_j \cap \text{supp}_k$  and  $F_2(x) = F_2(y)$ . In this case (A.1.1) and (A.1.2) simplify to

$$\bar{s} - b_j = \gamma \cdot \int_y^{\bar{s}} F_k(s)f_2(s)ds + \beta \cdot (1 - F_2(y)F_k(b_j)), \text{ and}$$

$$\bar{s} - b_k = \gamma \cdot \int_y^{\bar{s}} F_j(s)f_2(s)ds + \beta \cdot (1 - F_2(y)F_j(b_k))$$

respectively for all  $b_j, b_k \in (x, y)$ . Notice that in both expressions the integral is constant in the player's own bid. Since  $F_j$  and  $F_k$  coincide at  $x$  and  $y$ ,  $\int_y^{\bar{s}} F_k(s)f_2(s)ds = \int_y^{\bar{s}} F_j(s)f_2(s)ds$ . This shows that  $F_j(b) = F_k(b) \forall b \in (x, y)$ , which contradicts our assumption.

2.  $y \in \text{supp}_j \cap \text{supp}_k, x \in \text{supp}_j \setminus \text{supp}_k$ .  
Then by (A.1.1) and (A.1.2) at  $b = x$

$$\begin{aligned} \gamma \cdot \int_x^{\bar{s}} F_k(s)f_2(s)ds + \beta \cdot (1 - F_2(x)F_k(x)) &\leq \gamma \cdot \int_x^{\bar{s}} F_j(s)f_2(s)ds + \beta \cdot (1 - F_2(x)F_j(x)) \\ \Leftrightarrow \gamma \cdot \int_x^{\bar{s}} (F_k(s) - F_j(s))f_2(s)ds &\leq \beta F_2(x) \cdot \underbrace{(F_k(x) - F_j(x))}_{=0} = 0 \end{aligned}$$

By definition  $\gamma < 0$ , hence

$$\int_x^{\bar{s}} (F_k(s) - F_j(s))f_2(s)ds \geq 0.$$

If  $f_2(s) > 0$  for any  $s \in (x, y)$  this implies  $F_j(s) < F_k(s)$ , because by assumption  $F_j(b) \neq F_k(b) \forall b \in (x, y)$  and by Lemma 3 (no mass points)  $F_j$  and  $F_k$  are continuous. By assumption  $x \notin \text{supp}_k$ . So there exists an  $\varepsilon > 0$  such that  $F_k(x + \delta) = F_k(x)$  for all  $\delta$  such that  $0 < \delta < \varepsilon$ . But then

$$F_j(x + \delta) < F_k(x + \delta) = F_k(x) = F_j(x),$$

which is a contradiction, because  $F_j$  is a cumulative distribution function and as such is non-decreasing. ■

If  $f_2(s) = 0 \forall s \in (x, y)$ , then from Lemma 8  $[x, y] \subseteq \text{supp}_j \cap \text{supp}_k$ , a contradiction to the assumption  $x \notin \text{supp}_k$ .

3.  $x \in \text{supp}_j \cap \text{supp}_k, y \in \text{supp}_j \setminus \text{supp}_k$ .  
By (A.1.1) and (A.1.2) at  $b = y$

$$\begin{aligned} \gamma \cdot \int_y^{\bar{s}} F_k(s)f_2(s)ds + \beta \cdot (1 - F_2(y)F_k(y)) &\leq \gamma \cdot \int_y^{\bar{s}} F_j(s)f_2(s)ds + \beta \cdot (1 - F_2(y)F_j(y)) \\ \Leftrightarrow \gamma \cdot \int_y^{\bar{s}} (F_k(s) - F_j(s))f_2(s)ds &\leq \beta F_2(y) \cdot \underbrace{(F_k(y) - F_j(y))}_{=0} = 0 \end{aligned}$$

By definition  $\gamma < 0$ , hence

$$\int_y^{\bar{s}} (F_k(s) - F_j(s))f_2(s)ds \geq 0.$$

By (A.1.1) and (A.1.2) at  $b = x$

$$\begin{aligned} & \gamma \cdot \int_x^{\bar{s}} F_k(s) f_2(s) ds + \beta \cdot (1 - F_2(x) F_k(x)) \\ &= \gamma \cdot \int_x^{\bar{s}} F_j(s) f_2(s) ds + \beta \cdot (1 - F_2(x) F_j(x)) \\ &\Leftrightarrow \gamma \cdot \int_x^{\bar{s}} (F_j(s) - F_k(s)) f_2(s) ds = \beta F_2(x) \cdot \underbrace{(F_j(x) - F_k(x))}_{=0} = 0. \end{aligned}$$

$\gamma < 0$ , hence

$$\begin{aligned} & \int_x^y (F_j(s) - F_k(s)) f_2(s) ds + \underbrace{\int_y^{\bar{s}} (F_j(s) - F_k(s)) f_2(s) ds}_{\leq 0} = 0 \\ &\Rightarrow \int_x^y (F_j(s) - F_k(s)) f_2(s) ds \geq 0 \end{aligned}$$

If  $f_2(s) > 0$  for any  $s \in (x, y)$ , then this implies  $F_j(s) \geq F_k(s)$ . By assumption,  $F_j(b) \neq F_k(b) \forall b \in (x, y)$ , thus  $F_j(b) > F_k(b) \forall b \in (x, y)$ . By assumption  $y \notin \text{supp}_k$ . Hence, there exists an  $\varepsilon > 0$  such that  $F_k(y - \delta) = F_k(y) \forall 0 < \delta < \varepsilon$ . But then

$$F_j(y - \delta) > F_k(y - \delta) = F_k(y) = F_j(y),$$

a contradiction to the fact that  $F_j$  is a cumulative distribution function and as such is non-decreasing. If  $f_2(s) = 0 \forall s \in (x, y)$ , then from Lemma 8  $[x, y] \subseteq \text{supp}_j \cap \text{supp}_k$ , a contradiction to the assumption  $y \notin \text{supp}_k$ .

4.  $x \in \text{supp}_j \setminus \text{supp}_k, y \in \text{supp}_k \setminus \text{supp}_j$ .

By (A.1.1) and (A.1.2) at  $b = x$

$$\begin{aligned} & \gamma \cdot \int_x^{\bar{s}} F_k(s) f_2(s) ds + \beta \cdot (1 - F_2(x) F_k(x)) \leq \gamma \cdot \int_x^{\bar{s}} F_j(s) f_2(s) ds + \beta \cdot (1 - F_2(x) F_j(x)) \\ &\Leftrightarrow \gamma \cdot \int_x^{\bar{s}} (F_k(s) - F_j(s)) f_2(s) ds \leq \beta F_2(x) \cdot \underbrace{(F_k(x) - F_j(x))}_{=0} = 0 \end{aligned}$$

By definition  $\gamma < 0$ , hence

$$\int_x^{\bar{s}} (F_k(s) - F_j(s)) f_2(s) ds \geq 0.$$

A similar argument shows that at  $b = y$

$$\int_y^{\bar{s}} (F_k(s) - F_j(s)) f_2(s) ds \leq 0.$$

Consequently,

$$\begin{aligned} & 0 \leq \int_x^{\bar{s}} (F_k(s) - F_j(s)) f_2(s) ds \\ &= \int_x^y (F_k(s) - F_j(s)) f_2(s) ds + \underbrace{\int_y^{\bar{s}} (F_k(s) - F_j(s)) f_2(s) ds}_{\leq 0} \\ &\Rightarrow \int_x^y (F_k(s) - F_j(s)) f_2(s) ds \geq 0. \end{aligned}$$

If  $f_2(s) > 0$  for any  $s \in (x, y)$ , then this implies  $F_k(s) \geq F_j(s)$ . By assumption  $F_j(b) \neq F_k(b) \forall b \in (x, y)$ , thus  $F_k(b) > F_j(b) \forall b \in (x, y)$ . By assumption  $x \notin \text{supp}_k$ . Hence, there exists an  $\varepsilon > 0$  such that  $F_k(x + \delta) = F_k(x) \forall 0 < \delta < \varepsilon$ . But then

$$F_j(x + \delta) < F_k(x + \delta) = F_k(x) = F_j(x),$$

a contradiction to the fact that  $F_j$  is a cumulative distribution function and as such is non-decreasing.

If  $f_2(s) = 0 \forall s \in (x, y)$ , then from Lemma 8  $[x, y] \subseteq \text{supp}_j \cap \text{supp}_k$ , a contradiction to the assumption  $x \notin \text{supp}_k, y \notin \text{supp}_j$ .

Taking these four possible cases together, there cannot exist any interval  $[x, y]$  with  $F_1(x) = F_3(x)$ ,  $F_1(y) = F_3(y)$ , and  $F_1(b) \neq F_3(b) \forall b \in (x, y)$ .

Assume now that there exists an  $\bar{x} > b_0$  such that  $F_j(b) = F_k(b) \forall b \geq \bar{x}$  and  $F_j(b) > F_k(b), \forall b \in [0, \bar{x})$ . Players 1 and 3 must earn their equilibrium payoff at (or arbitrarily close to) zero, so by (A.1.1) and (A.1.2)

$$\begin{aligned} \gamma \cdot \int_0^{\bar{x}} F_k(s) f_2(s) ds + \beta \cdot (1 - F_2(0) F_k(0)) &= \gamma \cdot \int_0^{\bar{x}} F_j(s) f_2(s) ds + \beta \cdot (1 - F_2(0) F_j(0)) \\ &\Leftrightarrow \gamma \cdot \int_0^{\bar{x}} (F_j(s) - F_k(s)) f_2(s) ds - \beta F_2(0) [F_j(0) - F_k(0)] = 0 \\ \Leftrightarrow \gamma \cdot \underbrace{\int_0^{\bar{x}} (F_j(s) - F_k(s)) f_2(s) ds}_{>0} + \gamma \cdot \underbrace{\int_{\bar{x}}^{\bar{s}} (F_j(s) - F_k(s)) f_2(s) ds}_{=0} - \beta F_2(0) \underbrace{[F_j(0) - F_k(0)]}_{>0} &= 0 \quad (\text{A.1.3}) \end{aligned}$$

If  $f_2(s) = 0$  for all  $s \in (0, \bar{x})$ , then (A.1.3) simplifies to

$$-\beta F_2(0) \underbrace{[F_j(0) - F_k(0)]}_{>0} = 0.$$

This implies  $F_2(0) = 0$ , which is a contradiction, because Lemma 2 and  $f_2(s) = 0$  for all  $s \in (0, \bar{x})$  imply  $F_2(0) > 0$ .

If  $f_2(s) > 0$  for some  $s \in (0, \bar{x})$ , then  $\beta > 0$  and  $\gamma < 0$  imply that

$$\gamma \cdot \underbrace{\int_0^{\bar{x}} (F_j(s) - F_k(s)) f_2(s) ds}_{<0} - \beta F_2(0) \underbrace{[F_j(0) - F_k(0)]}_{\geq 0} < 0,$$

a contradiction to (A.1.3). Consequently, there can exist no  $b_0 > 0$  such that  $F_1(b_0) \neq F_3(b_0)$ .

**Lemma 10**  $F \equiv F_1 = F_3$  first order stochastically dominates  $F_2$ .

*Proof* If  $\bar{s}_2 = 0$ , then  $F_2(x) = 1 \forall x \geq 0$ . Hence,  $F$  first order stochastically dominates  $F_2$ .

Therefore, assume in the following that  $\bar{s}_2 > 0$ . By way of contradiction assume that there exists some  $b_0 \in [0, \bar{s}_2)$  such that  $F_2(b_0) < F(b_0)$ . Note that by Lemmas 8 and 9  $\text{supp}_j = [0, \bar{s}]$ ,  $j \in \{1, 3\}$ . Furthermore, by Lemma 4  $F_2(\bar{s}_2) > F(\bar{s}_2)$  and by Lemma 3 no player's equilibrium strategy has a mass point at any strictly positive bid. Then, there must exist an interval  $[\underline{t}, \bar{t}] \subseteq (0, \bar{s}_2)$  such that  $[\underline{t}, \bar{t}] \subseteq \bigcap_{i \in I} \text{supp}_i$ ,  $F_2(\underline{t}) < F(\underline{t})$ , and  $F_2(\bar{t}) > F(\bar{t})$ .  $[\underline{t}, \bar{t}] \subseteq \text{supp}_2$ . Therefore, player 2 must earn his expected equilibrium payoff at any bid  $x \in [\underline{t}, \bar{t}]$ ; that is, for every  $x \in [\underline{t}, \bar{t}]$

$$\begin{aligned} u_2^*(x, F, F) &= v_{22} [F(x)]^2 + v_{2j} (1 - [F(x)]^2) - x \\ &= v_{2j} + \alpha [F(x)]^2 - x \\ &= v_{2j} + \alpha [F(0)]^2, \end{aligned}$$

where the last equality follows from Lemma 2. Hence,

$$F(x) = \left( [F(0)]^2 + \frac{x}{\alpha} \right)^{\frac{1}{2}} \text{ for all } x \in [\underline{t}, \bar{t}]. \quad (\text{A.1.4})$$

Similarly,  $[\underline{t}, \bar{t}] \subseteq \text{supp}_j, j \in \{1, 3\}$ , implies that player  $j$ ,  $j \in \{1, 3\}$ , must earn his expected equilibrium payoff at any bid  $x \in [\underline{t}, \bar{t}]$ . Player  $j$ 's expected payoff from a bid,  $x \in [\underline{t}, \bar{t}]$ , is

$$u_j^*(x, F_2, F) = v_{jk} - \gamma \int_x^{\bar{s}_2} f_2(s) F(s) ds + \beta F(x) F_2(x) - x.$$

Player  $j$ 's payoff must be constant on  $[\underline{t}, \bar{t}]$ , that is,

$$\frac{du_j^*(x)}{dx} = \gamma F_2'(x) F(x) + \beta (F_2'(x) F(x) + F_2(x) F'(x)) - 1 = 0 \text{ for all } x \in [\underline{t}, \bar{t}].$$

This yields the following linear first order differential equation, which must hold for all  $x \in [\underline{t}, \bar{t}]$

$$F_2'(x)F(x)\alpha + F_2(x)F'(x)\beta = 1. \quad (\text{A.1.5})$$

Since  $F$  takes the form described in (A.1.4), the solution to (A.1.5) is

$$F_2(x) = \frac{2\alpha}{\alpha + \beta} F(x) + c \cdot [F(x)]^{-\frac{\beta}{\alpha}},$$

where  $c \in \mathbb{R}$  is a constant of integration.

By assumption  $\beta > \alpha$ , thus there exists a  $\delta > 0$  such that  $\beta = (1 + \delta)\alpha$  and we can write

$$F_2(x) = \underbrace{\frac{2}{2 + \delta}}_{<1} F(x) + c \cdot \underbrace{[F(x)]^{-(1+\delta)}}_{>0} \quad (\text{A.1.6})$$

By differentiating (A.1.6) we obtain

$$F_2'(x) = \frac{2}{2 + \delta} F'(x) - c \cdot \underbrace{(1 + \delta)}_{>0} \underbrace{F'(x)}_{>0} \underbrace{[F(x)]^{-(2+\delta)}}_{>0}. \quad (\text{A.1.7})$$

Suppose  $F(\bar{t}) < F_2(\bar{t})$ , then by continuity of the equilibrium strategies (Lemma 3)  $F(\bar{t} - \varepsilon) < F_2(\bar{t} - \varepsilon)$  for sufficiently small  $\varepsilon > 0$ . Considering  $x = \bar{t} - \varepsilon$  in (A.1.6) yields the necessary condition  $c > 0$ . Using this in (A.1.7) shows that  $F_2'(x) < F'(x)$  for  $x \in [\underline{t}, \bar{t}]$ . Hence,  $F(\underline{t}) < F_2(\underline{t})$ , a contradiction to the assumption that  $F(\underline{t}) > F_2(\underline{t})$ . Therefore, there exists no point  $b_0 \in [0, \bar{s}_2]$  such that  $F_2(b_0) < F(b_0)$ , and  $F$  first order stochastically dominates  $F_2$ .

**Lemma 11**  $F_2(x) = 1$  for all  $x \geq 0$

*Proof* Lemmas 2, 9, and 10 together imply  $F(0) = 0$ , hence by Lemma 2 player 2's expected payoff in equilibrium is  $v_{2j}$ . By way of contradiction assume that  $\bar{s}_2 > 0$ . Then, by the same argument as in the proof of Lemma 10 equation (A.1.6) must hold at every  $x \in \text{supp}_2$  with  $F(x) = \left(\frac{x}{\alpha}\right)^{\frac{1}{2}}$ . Player 2 may not randomize over strictly positive bids arbitrarily close to zero. Indeed, if such randomization did occur, because all players' equilibrium strategies are continuous over  $(0, \bar{s}]$  by Lemma 3,  $F(0) = 0$  and therefore

$$\lim_{\varepsilon \rightarrow 0} F(\varepsilon)^{-(1+\delta)} = \infty,$$

and  $F_2(0) < 1$  (under the assumption that  $\bar{s}_2 > 0$ ), then (A.1.6) would imply that  $c = 0$ , which is a contradiction to Lemma 10. Given that player 2 does not randomize over strictly positive bids arbitrarily close to zero, there exists a  $\underline{t} > 0$  such that  $\underline{t} = \inf\{t > 0 \mid t \in \text{supp}_2\}$ . Then,  $F_2(\underline{t}) = F_2(0)$ . By (A.1.1) player  $j$ 's expected payoff from a bid  $x \in (0, \underline{t}]$  is

$$u_j^*(x, F_2, F) = v_{jj} - \gamma \int_x^{\bar{s}} F(y) f_2(y) dy - \beta(1 - F_2(0)F(x)) - x.$$

$x \in (0, \underline{t}]$  is a best response for player  $j$  therefore  $u_j^*(x, F_2, F)$  must be constant over  $(0, \underline{t}]$ . It follows that  $F'(x) = \frac{1}{F_2(0)\beta}$  for  $x \in (0, \underline{t}]$ . From  $F(0) = 0$  follows that players 1 and 3 randomize uniformly over  $[0, \underline{t}]$  according to

$$F(x) = \frac{x}{F_2(0)\beta}, x \in [0, \underline{t}].$$

Continuity of  $F$  at  $\underline{t}$  yields

$$\frac{\underline{t}}{F_2(0)\beta} = \left(\frac{\underline{t}}{\alpha}\right)^{\frac{1}{2}} \Leftrightarrow \underline{t} = \frac{\beta^2}{\alpha} \cdot [F_2(0)]^2.$$

Consequently,

$$F(\underline{t}) = (1 + \delta)F_2(0).$$

Using this and  $F_2(\underline{t}) = F_2(0)$  in (A.1.6) yields

$$\begin{aligned} F_2(0) &= F_2(\underline{t}) \\ &= \frac{2}{2+\delta} F(\underline{t}) + c \cdot [F(\underline{t})]^{-(1+\delta)} \\ &= \frac{2}{2+\delta} (1+\delta) F_2(0) + c \cdot [(1+\delta) F_2(0)]^{-(1+\delta)}, \end{aligned}$$

which implies

$$c = \left( -\frac{\delta}{2+\delta} F_2(0) \right) [(1+\delta) F_2(0)]^{1+\delta} \leq 0.$$

This contradicts Lemma 10; therefore  $\bar{s}_2 = 0$ .

Altogether, this shows that player 2 stays out of the conflict in equilibrium. Hence, the equilibrium described in Proposition 1 is the unique equilibrium of  $\Gamma_{21}$ .

## B Proof of Proposition 5

*Proof* Under the assumption that all three players make positive bids with strictly positive probability and players 1 and 3 use identical strategies, i.e.  $F_1 = F_3 =: F$ , we know that  $\underline{s}_1 = \underline{s}_2 = \underline{s}_3 = 0$  and  $\bar{s}_2 = \bar{s}_1 = \bar{s}_3 =: \bar{s}$ . Moreover,  $\bar{s} \in (r_{jk}, r_{2j})$ ,  $j, k \in \{1, 3\}$ ,  $j \neq k$ , and player 2 cannot have a masspoint at zero. Assume that all players randomize continuously over  $[0, \bar{s}]$ . All players must earn their equilibrium payoff at  $\bar{s}$ , therefore player 2's expected payoff from a bid  $b \in (0, \bar{s})$ ,  $u_2(b, F) = v_{22}[F(b)]^2 + v_{2i}(1 - [F(b)]^2)$ , must be  $v_{22} - \bar{s}$ . This yields

$$F(x) = \begin{cases} 0 & x < 0 \\ \left[ \left(1 - \frac{\bar{s}}{r_{2j}}\right) + \frac{x}{r_{2j}} \right]^{\frac{1}{2}} & 0 \leq x \leq \bar{s} \\ 1 & x > \bar{s} \end{cases}.$$

Player  $j$ 's payoff must be  $v_{jj} - \bar{s}$ . Moreover, player  $j$  chooses his equilibrium strategy such that his expected payoff,  $u_j(b, F_2, F) = -b + v_{j2} + [v_{jj} - v_{j2}]F(b)F_2(b) + [v_{jk} - v_{j2}] \int_b^{\bar{s}} F_2(s)F'(s)ds$ , is maximized. The first order condition yields the first order differential equation

$$0 = F(x)F_2'(x)r_{j2} + F'(x)F_2(x)r_{jk} - 1.$$

Using the boundary conditions  $F_2(0) = 0$  and  $F_2(\bar{s}) = 1$  this yields

$$F_2(x) = \kappa F(x) - (\kappa - 1)F(x)^{-\frac{r_{jk}}{r_{j2}}}$$

with  $\kappa = \frac{2r_{j2}}{r_{j2} + r_{jk}} > 1$  and  $\bar{s} = r_{j2} \left[ 1 - \left(1 - \frac{1}{\kappa}\right)^{\kappa} \right]$ . Note that  $\bar{s} \in (r_{jk}, r_{j2})$  and  $F_2$  is strictly increasing.

In order to show that this equilibrium exhibits extremism, we need to show that  $F_2(x) \leq F(x) \forall x$ . All players' cdfs coincide for  $x < 0$  and  $x \geq \bar{s}$ . The centrist players put strictly positive mass on zero, thus  $F_2(0) < F(0)$ . For  $x \in (0, \bar{s})$ ,

$$F_2(x) = \kappa F(x) - (\kappa - 1)F(x)^{-\frac{r_{jk}}{r_{j2}}} = F(x) \underbrace{\left[ \kappa - (\kappa - 1)F(x)^{-\left(1 + \frac{r_{jk}}{r_{j2}}\right)} \right]}_{< \kappa - (\kappa - 1) = 1} < F(x).$$

Therefore,  $F_2$  first order stochastically dominates  $F$ .
