ABSTRACT

We have obtained the first high-dispersion observations of RX Pup in the wavelength region 1200-2000 Å with the International Ultraviolet Explorer. RX Pup has been classified a symbiotic star and has been compared to slow novae as well as to η Carinae. The anomalies that we observed in high-excitation lines in RX Pup such as He II, O III], C IV, and Si III] that show split line profiles, Doppler displaced multiple components, and possible inverse P Cygni profiles in N III] and N IV] suggest dynamic activity in circumstellar material that probably has the form of rings and/or gas streamers between the cool giant and the hot companion. The continuum observed by us in low dispersion is fairly flat in the wavelength region 1200-2000 Å and rises toward longer wavelengths in the region 2000-3200 Å. It cannot be due to a star earlier than A0 II. Alternatively it may be from an accretion disk. We find electron densities in the line-emitting region in the range 10^9 - 10^11 cm^{-3}, temperatures in the range 10,000-20,000 K, and linear sizes \lesssim a few \times 10^{13} cm. We find that the photoionizing radiation may be due to the presence of an unseen, hot subdwarf with most probable effective temperature in the range 75,000-90,000 K. Alternatively it may be due to an accretion disk around a secondary with boundary layer temperature \sim 10^6 K. Short-range as well as long-range monitoring of this very interesting object in the far-UV would be very helpful in understanding the nature of its peculiar properties and the connection between slow novae and symbiotic stars.

Subject headings: stars: binaries — stars: individual — ultraviolet: spectra

I. INTRODUCTION

When observed by Swings and Struve (1941), the peculiar emission-line object RX Puppis displayed a rich high-excitation emission spectrum featuring intense He II, [Fe vII], [Ne v], and other lines of > 100 eV ionization potential. As noted by Swings (1970), no evidence of a late-type absorption lines of Fe II, He I, and Mg II and the colors they argued that the continuum of RX Pup is that of a late B or early A giant (M_V \sim -3). They, moreover, attribute the variability to variations of a circumstellar dust shell around the B giant.

The presence of H_2O and CO absorption in RX Pup was recently demonstrated by means of 2 μm spectroscopy (Barton, Phillips, and Allen 1979). On the basis of the absorption band at 1.9 μm they confirmed the existence of a Mira variable (T_eff \sim 2400 K). They conclude that RX Pup is a symbiotic binary star in which the primary is a Mira variable. Recently, Whitelock (1981) has reported a 580^4 period for the Mira in RX Pup. Night to night variations in the Balmer line intensities in 1975 March were reported by Swings and Klutz (1976). Multicomponent P Cygni profiles of the Balmer lines and the stronger Fe II lines were detected in 1976 (Klutz, Simonetto, and Swings 1978), and sharp blueshifted absorptions in the Balmer lines ranging from -1100 to -230 km s^{-1} were seen in 1975, 1976, and 1977. Moreover, the 1977 H_γ or H_δ profiles show a strong emission line with a very steep blue wing, a sharp
emission peak, and a broad red wing with absorption at +250 km s⁻¹ (Klutz, Simonetto, and Swings 1978).

We present here the first set of high-dispersion UV observations of RX Pup. Anomalous line profile structure observed in a number of high-excitation emission lines is discussed in context with a model that includes streams and complex mass motions in the system.

II. OBSERVATIONS AND DATA ANALYSIS

a) UV Lines and Continuum

IUE spectral data were obtained exclusively in the large 10° × 20° entrance aperture of the satellite spectrometer (Boggess et al. 1978). The Fine Error Sensor (FES) monitor on IUE obtained an apparent magnitude mᵥ ≈ 10.

We obtained IUE low-resolution short wavelength prime (SWP) and long wavelength redundant (LWR) spectra of RX Puppis on 1980 September 20 as well as one 102 min high-dispersion SWP spectrum, all under IUE observing program ZACAM. We find split line profiles of the He II 1640.3 Å, O III 1660.8 and 1666.1 Å, and Si III 1892 Å lines; multiple emission components in the C IV 1548.2 and 1550.8 Å lines; and asymmetric profiles in the Si IV 1393.7, N IV 1486.5 Å, and N III 1749.7 Å, 1754 Å lines. The low-resolution spectra reveal lines in order of increasing wavelength of O I, Si IV, O IV, N IV, C IV, He II, O III, N III, Si II, Si III, C III in the LWR and C IV + [O III], He II, Mg II, [Ar IV] + He I and a number of O III lines.

Table 1 presents the line identifications in the high-
As can be seen from Table I, there is considerable structure in the lines observed. The emission components are indicated by (e) in the fifth column, while possible absorption is indicated by (a). The C iv doublet shows components at the rest wavelengths of the two lines as well as two components redshifted from the rest wavelengths by \( \sim 40 \text{ km s}^{-1} \) and \( \sim 90 \text{ km s}^{-1} \). We note that the internal errors of \( \text{IUE} \) of \( \sim 0.05 - 0.10 \text{ Å} \) (Bruhweiler, Kondo, and McCluskey 1980) correspond to \( \sim 10 - 20 \text{ km s}^{-1} \) uncertainty at the C iv wavelengths. The He ii \( 1640.33 \text{ Å} \) line shows two components, the strongest centered near the rest wavelength, the weaker redshifted by \( \sim 170 \text{ km s}^{-1} \). The O iii] \( 1660.80 \text{ Å} \) and \( 1666.15 \text{ Å} \) lines show two components, each located more or less symmetrically shortward and longward of the rest wavelength. The two components have a total separation of \( \sim 55 \text{ km s}^{-1} \), indicating possibly the presence of a ring system. The Si iii] \( 1892.03 \text{ Å} \) line shows a similar structure with a total separation of the two components \( \sim 60 \text{ km s}^{-1} \). Due to the uncertainties involved, the O iii] and Si iii] lines arise from identical regions. The C iii] \( 1908.7 \) Å line shows a single component. Finally, the N iv] and N iii] lines show asymmetric profiles. We see emission components in which the blue wings of the lines are extended with emission in the red wing dropping abruptly. The situation may be similar in the Si iv line, although in this case the high-dispersion signal is weak and, therefore, the structure uncertain. We note that the extended shortward wing emission observed in a number of the spectral lines observed in the UV are exactly opposite to what Klutz, Simonetto, and Swings (1978) observed in the profiles of Hy, H0 in 1977. It is obvious that such complex line structure should be monitored for time variations. Because the profiles change dramatically as one proceeds through different stages of ionization, one should not be surprised to see large changes in emission as the geometry of the object alters. The separation of the N iv] peak from the sharply dropping longward wing of this line is \( \sim 200 \text{ km s}^{-1} \) and \( \sim 150 \text{ km s}^{-1} \) for the N iii] lines.

From the above discussion, we see that there is a tendency for larger velocity separations to be associated with higher ionization stages, the largest ones seen in the He ii, N iv] profiles. Moreover, it is hard to see how a single object could account for such complicated profiles. It should be pointed out, however, that no systematic radial velocity change has so far been detected. The predominance of longward emission—or absorption—features probably argues for a gas stream from the red component falling toward a hot secondary. Symmetric components—as seen in the O iii], Si iii] lines—argue for a ring system. Rotation as an explanation of doubling of optical emission lines has also been proposed by Allen for a number of symbiotics (see Allen 1980). We suspect that the multiple component structure of the lines in RX Pup would change with time as the two stars and the gas in between them change their orientation with respect to the Earth, and this would be an easy test for binarity. In this picture, higher orbital velocities would be associated with higher ionization closer to the hot secondary.

Finally, we note that the 1548 Å component of C iv is weaker than the 1550 Å component, although the expected ratio should be 2:1 for an optically thin gas and 1:1 for an optically thick one. A similar situation prevails in other symbiotic stars, such as AG Peg (Keyes and Plavec 1980), Z And (Altamore et al. 1981), and V1016 Cyg (Nussbaumer and Schild 1981). Other resonance lines—N v, Si iv—show this effect too. Collisonal de-excitation of the upper level and high optical depths may contribute to an alteration of the 2:1 ratio, although Nussbaumer and Schild (1981) have shown that this meets with certain difficulties and may not be necessary to involve such mechanisms: a hot \( (T \sim 10^5 \text{ K}) \) diffuse interstellar medium may be sufficient. Since the presence of this component of the interstellar medium has recently been detected with \( \text{IUE} \) near the Sun (Bruhweiler and Kondo 1981), this mechanism is very plausible. It is still difficult, though, to explain why the 1548 Å line would be weaker than the 1550 Å line. A broad P Cygni absorption component of the 1550 line may be required, with \( \sim 400 \text{ km s}^{-1} \) as suggested by Keyes and Plavec for AG Peg, making the RX Pup C iv profiles very complicated indeed.

In Figure 1 we show the SWP (top) and LWR (bottom) low dispersion spectra of RX Puppis. In Figures 2, 3, 4 and 5 we show the N iv], C iv], O iii], He ii, Si iii] high-resolution profiles discussed above. These figures show how important it is to obtain high-dispersion spectra of symbiotic stars, whenever feasible. On the basis of the low-dispersion spectra alone, one may be tempted to conclude that RX Pup appears similar to RW Hya (Kafatos, Michalitsianos, and Hobbs 1980). A comparison, though, of high-dispersion spectra of these two stars reveals fundamental differences: Strong dynamic activity is suggested in the spectra of RX Pup. On the other hand, strong emission in N v, O i, Si iv, O iv, He ii, O iii], N iii], Si iii], C iii], C iv], Mg ii, and O iii] was seen in RW Hya with no indication of split profiles or absorption features (Kafatos, Michalitsianos, and Hobbs 1980). In another respect, the differences between these stars were noted by Feast, Robertson, and Catchpole (1977): RW Hya is a symbiotic star without dust, whereas RX Pup (along with RR Tel, a slow nova) is a member of a symbiotic system that exhibits thermal dust emission (cf. Swings and Allen 1972). Moreover, such objects as RR Tel, RX Pup, and PKS 280—2.1 (Feast, Robertson, and Catchpole 1977) have been compared to slow novae, but a clear distinction between novae and peculiar emission line stars has not been established.
In Figure 1 a continuum is evident, weak but slowly rising toward longer wavelengths in SWP and quite strong and rapidly rising in LWR. It is not possible to obtain an exact value of the extinction from the 2200 Å dip, although it is clear that absorption is not negligible (but still $E_{B-V} \lesssim 1$). Klutz, Simonetto, and Swings (1978) obtained a value of ~1 kpc for the distance to this object. Using a galactic absorption law (Kafatos, Michalitsianos, and Hobbs 1980), we find $E_{B-V} \approx 0.7$. Klutz, Simonetto, and Swings (1978) favor $E_{B-V}$ in the range 0.7–1.0. Feast, Robertson, and Catchpole (1977), on the other hand, obtained $E_{B-V} \sim 0.3$. We also estimated $E_{B-V}$ from the theoretical ratios of the He II lines (cf. Seaton 1978) and found that $E_{B-V} \geq 0.7$. This method is, though, suspect because it is not clear how the ratios would vary at the high densities prevalent in the RX Pup nebula. Henceforth, in our analysis, we will assume values of $E_{B-V} = 0.3$ or 0.7.

The simplest approach one can take to explain the continuum is to attribute it to a photospheric continuum from a hot companion. This has been a useful approach for a number of binary stars (Parsons 1981). In symbiotic stars, though, this approach has been generally unsatisfactory (Michalitsianos et al. 1982; Kafatos 1981). We find that the UV continuum mimics that of an early...
F to an early A type, depending on the value of $E_{B-V}$ (A8 II, $M_B \sim -1.9$ for $E_{B-V} = 0.3$; and A0 II, $M_B \sim -3.16$ for $E_{B-V} = 0.7$). If the continuum is from a star it cannot be earlier than A0 (because it would have been brighter than 9th magnitude at the time of our observation). From this we deduce that there is no evidence for a B star in RX Pup (cf. Klutz, Simonetto, and Swings 1978).

We suspect that alternative continuum emission mechanisms may be required: nebular bound-free and free-free continuum (see § IIb) and/or continuum from a boundary layer and accretion disk (see § III).

Observations over different times would help us in discerning the nature of the continuum (if it is constant, it would probably be from star; if it varies, it would be from an accretion disk or a gas stream).

b) Nebular Parameters

The UV spectrum of RX Pup is dominated by allowed and semiforbidden lines. In the previous section we saw that the high-resolution profiles indicate a number of distinct regions in velocity space. In order to obtain information about the densities and temperatures prevalent in the line emitting regions, we make the simplifying assumption that uniform densities and temperatures prevail in these regions; the densities and temperatures we thus obtain should be taken as rough values. This simplifying assumption turns out to be fairly valid.

The semiforbidden lines are sensitive to the density. We obtain lower limits on the electron density, $n_e \geq 10^6$ cm$^{-3}$, from the absence of the C III 1906.7 Å line and the N IV 1483.2 Å line (Loulergue and Nussbaumer 1976). Moreover, the presence of the N IV 1486.5 Å line implies $n_e \sim 10^{11}$ cm$^{-3}$, and the presence of the C III 1908.7 Å line implies $n_e \sim 2 \times 10^{10}$ cm$^{-3}$ (Osterbrock 1970).

The strength of the C III 1908.7 Å line relative to the λλ1174.93–1176.38 C III multiplet which was possibly detected gives estimates of the density as well as upper limits of the electron temperature $T_e$ (cf. Loulergue and Nussbaumer 1974, 1976; Nussbaumer and Schild 1979). We find that $T_e \lesssim 30,000$ K and $10^9 \lesssim n_e \lesssim 10^{10}$ cm$^{-3}$. Similarly, the N III multiplet can be used to obtain estimates of $n_e$ (cf. Altamore et al. 1981; Nussbaumer and Storey 1979). We find that $n_e \sim 2 \times 10^{10}$ cm$^{-3}$, although a density gradient may be necessary. The situation with the O IV multiplet is less clear due to the weakness of the lines: higher densities ($n_e \sim 10^{11}$ cm$^{-3}$) may be required, but deeper exposures are needed (cf. Flower and Nussbaumer 1975).
The weakness or total absence of forbidden-line emission also argues for high densities. The presence of the [Ne v], [Ne iii] lines is questionable. From Kafatos and Lynch (1980) we find that the [Ne v] 1575.2 Å, [Ne iv] 1601.5 Å, and [Ne iii] 1814.8 Å lines get collisionally depopulated near \( n_e \sim 10^9 \text{ cm}^{-3} \). Since no [Ne iv] feature was seen, if the [Ne iii], [Ne v] lines are present this would imply \( n_e \lesssim 10^{10} \text{ cm}^{-3} \). The only forbidden lines that may exist in the low-resolution LWR spectrum are [O iii] 22321.1 Å (although blended with C ii 22325–22328) and [Ar iv] 13853.6 Å (again blended with He i 22829.1). It may indeed be the case that no forbidden lines are present in the IUE spectra. The absence of the [O ii] 22471 implies \( n_e \gtrsim 10^9 \text{ cm}^{-3} \) for \( T_e \sim 15,000 \text{ K} \) (Kafatos and Lynch 1980). Klutz and Swings (1981) obtained recently coude spectra of RX Pup. They find that the ratio of the [O iii] 4363 Å to the Ni + N lines is high, indicating high densities.

From the previous discussion it follows that the various semiforbidden and forbidden intensities imply densities in the range from \( 10^9 \) to a few times \( 10^{10} \text{ cm}^{-3} \), with upper limits not more than \( 10^{11} \text{ cm}^{-3} \). All lines could arise from a single density region (\( n_e \sim 10^{10} \text{ cm}^{-3} \)), although this statement depends obviously on whether a single value of \( T_e \) applies to all lines.

The absolute intensities of the UV lines can be used to estimate the relative ionic abundances in the line emitting region. For densities up to a few times \( 10^9 \) or a few times \( 10^{10} \text{ cm}^{-3} \) the semiforbidden line strengths are proportional to \( n_e^2 L \Omega \), where \( L \) is the path length through the emitting region (Kafatos, Michalitsianos, and Hobbs 1980) and \( \Omega \) the solid angle of the region. This expression reduces to \( n_e^2 L \) for a spherical region, where \( L \) is the size. If the region, however, is in the form of streams, rings, or a disk, we have to take into account the geometrical effects of observation. In general, we can always write it as \( n_e^2 L^2 f_g \), where \( f_g \leq 1 \) is a factor depending on the geometry of the region relative to the line of sight and the equality applies in the spherical case. In the general case, \( L \) is understood to be the largest characteristic size of the region (e.g., the diameter of the disk, etc.). Since the line intensities are proportional to \( n_e^2 L^2 f_g \), if we set \( f_g = 1 \) and we substitute a value for \( n_e \sim (10^9 - 10^{10}) \text{ cm}^{-3} \), the resultant value for \( L \) is a lower limit.

In Table 2 we show the relative ionic abundances for the following adopted parameters: \( E_{B-V} = 0.3 \), \( T_e = 15,000 \text{ K} \), distance \( d = 1000 \text{ pc} \) (Klutz, Simonetto, and Swings 1978). The inequalities apply because some N ii,

$^a$ Some N ii, O ii, and Si v should be present.
$^b$ From upper limit to the [O ii] line flux.
$^c$ Applicable if Mg ii emission comes from line emission region rather than being chromospheric.

O ii, and Si v should be present, although the exact amounts are unknown due to the lack of observable lines. The Mg ii emission may, on the other hand, arise from the chromosphere of the red giant, although single Miras observed before (Kafatos, Michalitsianos, and Hobbs 1980) show much weaker Mg ii emission. In Table 3A we show the lower limit of the larger dimension of the region $L$, for values of electron density $n_e = 10^9$, $10^{10}$ cm$^{-3}$. The ionic abundances depend very weakly on the value of the extinction assumed. We computed a different model for $E_{B-V} = 0.7$ with substantially the same results, except for He i and He ii. The values of $L$ change by a factor of ~3 when $E_{B-V} = 0.7$ is assumed, and are shown in Table 3B.

The chemical abundances for the nebular model of Table 2 are cosmic for nitrogen and oxygen. Carbon is, however, depleted by a factor of ~7 and silicon by ~4 with respect to cosmic abundances. Similar situation prevails in other symbiotic stars—e.g., R Aqr (Michalitsianos, Kafatos, and Hobbs 1980) and RW Hya (Kafatos, Michalitsianos, and Hobbs 1980).

The nebular parameters depend strongly on the assumed value of $T_e$. Since forbidden line emission is weak or totally absent, we have no independent way to determine $T_e$. We already saw that a probable upper limit for $T_e$ is ~30,000 K. Moreover, we can rule out chromospheric transition region temperatures of the order of or greater than 100,000 K. At $T_e ~ 10^5$ collisional ionization would be the dominant mechanism and ionic abundances would be different than the values listed in Table 2 (cf. Kafatos 1973). We believe that $T_e$ is in the probable range ~10$^4$ to 2 x 10$^4$ K expected for a nebula that is photoionized, with an upper limit of ~30,000 K. Without an independent way to determine the product $n_e^{-2}E_f$ or the chemical abundances, the value $T_e = 15,000$ K adopted in Table 2 is only suggestive. Even with the uncertainties involved, however we disagree with the contention of Altamore et al. (1981) that a transition region around the cool star in Z And is required for the line emission. A similar analysis can be applied to that symbiotic star too, and we find that temperatures ~10$^5$ K are ruled out as in RX Pup for similar reasons. We agree, however, with Nussbaumer and Schild (1981), who find that photoionization dominates in V1016 Cyg as well.

We also note that for $E_{B-V} = 0.3$ free-free and bound-free continuum would contribute about a fifth of the observed continuum in the LWR region of the spectrum and slightly less than this value in the SWP. For $E_{B-V} = 0.7$, $T_e = 15,000$ K the theoretical continuum would be roughly half of the observed continuum in the LWR region. It suffices to say here that bound-free and free-free continua make a substantial contribution to the observed continuum, particularly for the higher values of $E_{B-V}$ considered.

The Bowen resonance-fluorescence lines of O iii can be used to estimate the number of photons below 228 Å (the He ii Lyman continuum photons). The 3132.86 Å O iii line contributes ~0.31 of the total fluorescence line flux (Osterbrock 1974). Moreover, the overall fraction of He ii Lyz photons converted into Bowen resonance-fluorescence photons is ~0.5 (Osterbrock 1974). Since the nebula is thick in the He ii Lyman lines, recombinations of He iii to all levels $n \geq 2$ yield He ii Lyz photons (Seaton 1960). The observed 3132.86 Å flux, therefore, implies that $N(hv > 54.4$ eV) $\approx 4.6 \times 10^{44}$ s$^{-1}$ for $E_{B-V} = 0.3$ and $N(hv > 54.4$ eV) $\approx 3.1 \times 10^{45}$ s$^{-1}$ for $E_{B-V} = 0.7$.

### III. DISCUSSION AND CONCLUSIONS

We saw in §IIb that photoionization seems to dominate in the line emitting region of RX Pup. The question remains: What is the source of the UV photons? In the present section we attribute the photoionization either to (a) a hot companion or (b) to an accretion disk/ boundary layer. A combination of these two cases (a) and (b) is, of course, also possible.
a) Hot Companion

If we attribute the observed continuum to an early F or an early A star (§ IIa), we find that such a star does not emit enough ionizing photons to produce the line emitting region: We need a considerably hotter star in this case.

We have obtained an approximate distribution of the ionizing continuum flux $F_\nu$ below 912 Å by using the relative ionic abundances of Table 2 and evaluating the product $F_\nu a_i$ at the threshold of each ion, where $a_i$ is the photoionization cross section (cf. Osterbrock 1974). In this procedure, we have assumed that the size of the ionization region for each ion is constant, an obvious simplifying assumption. We have compared this approximate flux $F_\nu$ with the LTE models of Hummer and Mihalas (1970). We find that the effective temperature of the secondary star in the approximate range $4 \times 10^4 \text{ K} \leq T_{\text{eff}} \leq 10^5 \text{ K}$: If $T_{\text{eff}}$ were lower than the lower limit (if $T$ were, say, equal to 30,000 K), the ionizing flux—whether blackbody or from the model atmosphere—would be too small below $\sim 760$ Å to explain the ionization beyond Si iii; if, on the other hand, $T_{\text{eff}}$ were above the upper limit, then there would be too much flux below 160 Å and the N v, O v lines should be present and strong in the SWP spectrum of RX Pup. We also find that a non-LTE pure hydrogen model atmosphere at $T_{\text{eff}} = 55,000$ K (Holberg et al. 1980) provides a reasonable fit (within a factor of $\sim 2$) to our estimated values of $F_\nu$, the greater discrepancies occurring at the C iii, He ii, Si ii, and Mg ii ionization limits. In what follows, for both the photoionizing flux from a hot companion and/or the photoionizing flux from a boundary layer-accretion disk we will assume that the temperatures are in the range 40,000 K–100,000 K.

From the Strömgren relation we find that the number of ionizing photons, $N_{\nu}$, is $\sim 4.9 \times 10^{45} \text{ s}^{-1}$ for $E_{B-V} = 0.3$ and $\sim 8.6 \times 10^{46} \text{ s}^{-1}$ for $E_{B-V} = 0.7$. The results of Hummer and Mihalas (1970) show that the overall number of ionizing (beyond the Lyman limit) photons in their models is not greatly different from the estimated number of photons that arise from a blackbody. We therefore use the blackbody formula and find the values of $R_{\text{a}}$, the radius of the secondary, required to produce enough ionizing photons $N_\nu$ values that are shown in Table 4A for the two values of $E_{B-V} = 0.3$, 0.7 and the two limits of the effective stellar temperature, $T_{\text{eff}} = 40,000$ K and 100,000 K. We see that if a hot companion is responsible for the photoionizing radiation, such a star would be located in the central stars of planetary nebulae region and near the location of the hot companion in RW Hya (Kafatos, Michalitsianos, and Hobbs 1980).

The estimated number of photons with energy $\geq 54.4$ eV (§ IIb) can be compared with the theoretical values

* Case A: $E_{B-V} = 0.3$, $T_{\text{eff}} = 40,000$ K, $N_\nu = 4.9 \times 10^{45} \text{ s}^{-1}$, $L_{\text{BD}} \text{ UV} = 30 L_{\odot}$.
* Case B: $E_{B-V} = 0.7$, $T_{\text{eff}} = 40,000$ K, $N_\nu = 8.6 \times 10^{46} \text{ s}^{-1}$, $L_{\text{BD}} \text{ UV} = 300 L_{\odot}$.
* Case C: $E_{B-V} = 0.3$, $T_{\text{eff}} = 100,000$ K, $N_\nu = 4.9 \times 10^{45} \text{ s}^{-1}$, $L_{\text{BD}} \text{ UV} = 30 L_{\odot}$.
* Case D: $E_{B-V} = 0.7$, $T_{\text{eff}} = 100,000$ K, $N_\nu = 8.6 \times 10^{46} \text{ s}^{-1}$, $L_{\text{BD}} \text{ UV} = 300 L_{\odot}$.

Note: $T_{\text{BD}}$, boundary layer temperature (K); $N_\nu$, number of ionizing ($h\nu \geq 13.6$ eV) photons (s$^{-1}$); $L_{\text{BD}} \text{ UV}$, portion of disk and boundary layer luminosity emitted in the IUE spectral range, determined from the observed flux and the distance ($L_{\odot}$); $R_{\text{a}}$, radius of secondary (in 10$^6$ cm); $M_{\text{acq}}$, accretion rate onto secondary (in 10$^{-4}$ $M_\odot$ yr$^{-1}$); $L_{\lambda}$, $L_T$, $L_{\text{BD}}$, disk, total, and Eddington luminosities ($L_{\odot}$); $\beta$, efficiency of accretion; $i$, angle between the normal to the orbital plane and the line of sight.

of the same quantity from Hummer and Mihalas (1970). We find that models with $T_{\text{eff}} \gtrsim 90,000 \, \text{K}$ and $4.5 \lesssim \log g \lesssim 5.5$ provide reasonable agreement. The effective stellar temperature can be as high as $10^4 \, \text{K}$ (log $g$ = 6 model of Hummer and Mihalas 1970), but certainly not above this value or lower than $\sim 70,000 \, \text{K}$.

We conclude that effective temperature values above halfway in the range 40,000 K–100,000 K are probably the best estimates (say, $T_{\text{eff}} \gtrsim 75,000 \, \text{K}$ but still $T_{\text{eff}} \lesssim 10^3 \, \text{K}$).

b) Accretion Disk around a Secondary

The photoionizing photons may alternatively arise from an accretion disk and its inner boundary layer region. As we noted, the velocity structure of the line profiles is suggestive of rings of material around and/or streamers onto a secondary. We note that although our model of an accretion disk may not explain the UV spectral properties of RX Pup at all times, it nevertheless presents an interesting theoretical limit: if accretion fully develops, the parameters required are given below.

We use the relations derived by Kafatos (1981) to estimate the various accretion parameters (see also Bath et al. 1974; Tylenda 1977; Lynden-Bell and Pringle 1974). These parameters are shown in Table 4B and are the following: $R_b$ is the radius of the secondary in $10^6 \, \text{cm}$; $M_{\text{acc}}$ is the accretion rate on the secondary in $10^{-8} \, M_\odot \, \text{yr}^{-1}$ (we have assumed the mass of the secondary to be equal to $1 \, M_\odot$); $L_i$ is the disk luminosity in solar units; $L_T$, $L_{\text{Edd}}$ are the total (boundary layer plus disk) and Eddington luminosities, respectively; $\beta$ is the efficiency of accretion defined by $\beta = L_T/L_{\text{Edd}}$; and $i$ is the efficiency angle between the normal to the orbital plane and the line of sight.

As in § IIIa we have assumed that the maximum temperature in the inner region of the disk, $T_{\text{disk}}$, in the range 40,000 K–100,000 K. We compute the accretion parameters for two values of $E_{\text{ion}}$ = 0.3, 0.7. The number of ionizing photons emitted by the boundary layer is set equal to $4.9 \times 10^{45} \, \text{s}^{-1}$ for $E_{\text{ion}}$ = 0.3 and $8.6 \times 10^{45} \, \text{s}^{-1}$ for $E_{\text{ion}}$ = 0.7 (the values shown in Table 4B are for the case of the ionized region being ionization bounded) as obtained by the analysis of § II. Finally, the observed UV luminosity in the IUE range (i.e., for $1200 \lesssim \lambda \lesssim 3200 \, \text{Å}$), $L_{\text{obs}}^{\text{UV}}$, can be obtained if we set the distance equal to 1000 pc; it is equal to $30 \, L_\odot$ for $E_{\text{ion}}$ = 0.3, 300 $L_\odot$ for $E_{\text{ion}}$ = 0.7. In Table 4B we distinguish four cases: cases A and B for $T_{\text{disk}} = 40,000 \, \text{K}$, cases C and D for $T_{\text{disk}} = 100,000 \, \text{K}$, cases A and C for $E_{\text{ion}}$ = 0.3, cases B and D for $E_{\text{ion}}$ = 0.7. We first note that since $T_{\text{disk}}/T_g (r = 2.25 \, R_\odot) \sim 5.81$ (Tylenda 1977), the SWP and LWR flux would be due primarily to the disk if $T_{\text{disk}} \lesssim 80,000 \, \text{K}$. For $T_{\text{disk}} = 40,000 \, \text{K}$ the disk would mimic an F2 star whereas for $T_{\text{disk}} = 100,000 \, \text{K}$ it would mimic a B4 star. The observed IUE continuum flux could, therefore, arise from an accretion disk. We note, however, that since the densities in the line emitting region are in the range $\sim 10^{12}-10^{14} \, \text{cm}^{-3}$, the semi-forbidden lines cannot arise in a disk where the expected densities would be $n_e \gtrsim 10^{18} \, \text{cm}^{-3}$ in the inner region. The number of photons with $\hbar \nu \gtrsim 54.4 \, \text{eV}$ obtained by the O III fluorescence line analysis can be used to estimate the temperature of the boundary layer. We have $N(\hbar \nu \gtrsim 54.4 \, \text{eV})/N(\hbar \nu \gtrsim 13.6 \, \text{eV}) \approx 0.095, 0.037$ for $E_{\text{ion}}$ = 0.3 and 0.7, respectively. Using the blackbody formulae, we find that $T_{\text{ax}} \approx 1.1 \times 10^4 \, \text{K}$ and $9 \times 10^4 \, \text{K}$, respectively. We therefore see that the boundary layer temperature is again closer to the upper limit of the estimated range $\sim 10^5 \, \text{K}$.

We see from Table 4B that the derived radius of the companion star may indeed indicate that a main sequence star (cases A, B, and D), rather than a hot subdwarf, is present. Accretion rates for cases A, B, and D are also more indicative of accretion onto a main sequence star (Michalitsianos et al. 1981). A similar situation has been shown to exist in CI Cygni (Stencel et al. 1982; Bath and Pringle 1980). The small values of $L_T/L_{\text{Edd}}$ indicate, though, that the supercritical accretion model of Bath (1977) does not apply, at least at present.

Whether photoionization from a hot subdwarf or photoionization from a boundary layer/accretion disk around a cooler main sequence star is required is unclear at present. Undoubtedly, symbiotic stars where a hot secondary is present exist (e.g., R. W. Hya; see Kafatos, Michalitsianos, and Hobsbs 1980); as well as symbiotic stars where a main sequence secondary—with an accretion disk—exists (e.g., CI Cyg; see Stencel et al. 1981).

A possible test may be provided by future observations. Using the effective temperature of the Mira of 2400 K (Barton, Phillips, and Allen 1979) and the theoretical relations for Miras of Willson (1980), we find the expected period of the Mira in RX Pup to be $\gtrsim 700$ days (close to the value of 580 days reported by Whitehler 1981), its radius $\lesssim 600 \, R_\odot$, its mass $\sim 2-3 \, M_\odot$, and its luminosity $\sim 10^4 \, L_\odot$. The expected mass loss rate would be $\sim 3 \times 10^{-7} \, M_\odot \, \text{yr}^{-1}$, less than all the values of the accretion rate of Table 4B: Mass loss, therefore, is enhanced, very likely because of binarity. If the Mira were filling its Roche lobe, the system would have a period $\lesssim 8 \, \text{yr}$. Observations in the next few years of this very interesting object would be very important to see whether a short orbital period exists, i.e., a Roche overflow situation. In that case a main sequence secondary would be indicated (otherwise the disc luminosity would be excessive). Monitoring RX Pup is important, in any case, because it appears that it is returning to a symbiotic phase (Klutz and Swings 1981).

One thing is clear: The peculiar line profiles in RX Pup would be hard to interpret in terms of a single star only. If we set the stream velocity ($\sim 100-200 \, \text{km s}^{-1}$) equal to the escape velocity at distance $r$ from the star, we find that $r \gtrsim 10^{12} \, \text{cm}$, comparable to the radius of the line emitting region. The symmetric profiles argue for the presence of rings.

We thank R. Viotti and particularly J. P. Swings for useful comments and suggestions.
